The commonest syndrome is an acute *anxiety state*, combining motor, visceral, and mental symptoms. The anxiety is exhibited by tremors and weakness, pallor, sweating, tachycardia, sensitivity to noise, disturbed sleep, irritability. Noises startle, a remark may lead to tears or a storm of anger. Such an acute nervous reaction is not a static picture but fluctuates from day to day in response to treatment and upon exposure.

Exhaustion is not the basic cause of a true neurosis. It will, however, set in motion symptoms of an acute nervous state. Such symptoms if properly cared for clear up, yet improperly treated and under certain circumstances the acute reaction is the starting point for a chronic neurotic state. The British report of *Psychiatric Casualties*⁹ states, "Physical exhaustion is the commonest precipitating cause of nerves." The importance of exhaustion as a factor in causing such disorders is stressed by Farrell and Appel.¹⁰ "The highest admission rates (for neuropsychiatric cases) occur in troops in actual combat. In overseas theatres where there is no active combat the rates are lower than among troops within the United States. The per cent of neuropsychiatric casualties rises in direct proportion to the length of active combat duty."

TREATMENT

Prevention—Prevention is the first step, yet not always attainable. In industry the hours of work may be reduced, in warfare the situation commands the man. Then, too, though it might be advisable from the medical standpoint to relieve fighting men before profound fatigue sets in, yet from the military aspect such relief may not be available or practical. Any recommendations can be carried out only in the framework of reality situations.

Prevention and treatment may be carried out along three lines: physical, psychic and drug—or, to put it in alliterative form, muscular, mental and medicinal methods can be used.

Physical Conditioning—First is the selection of the physically fit, as for example the choice of lean young men for tropical service. Next is training. Toughening marches and physical drill will improve muscle action and enable the soldier to withstand the rigors of combat. Such training helps muscles and the circulation, and increases general stamina as well. Pilots are encouraged to exercise and play ping pong, swim, do calisthenics, rather than to mope, drink, and play cards. Soldiers should continue training and recreation during inactive periods. We must build the capacity for prolonged exertion.

Mental Attitude—A decisive element in fatigue is the mental attitude. The soldier who is absorbed in his task, who is striving for a goal, can draw upon an almost inexhaustible reservoir of energy. He who feels unhappy, mistreated, defeated, wastes his present energy and dissipates reserves. This applies equally to the man in industry.

The stamina of the soldier is closely related to his morale. The fighting man who thoroughly believes that he is fighting for his family, who has faith in his leaders, who identifies himself with "its cause," can march farther, hold out longer. So, too, the employee whose job is interesting and who feels the reward is fair will ignore fatigue. A mother nursing her sick child can keep going day and night, unmindful of tiredness because her duty is a labor of love.

We are all familiar with the picture of the young woman returning home from a hard day's work, bored, unhappy, and tired. She flops into bed, too exhausted to eat. In this state of near stupor she lies, when suddenly the phone rings and an almost forgotten but highly desired boy friend invites her to a night club. She is electrified into energy. With singing voice and elastic step she bathes and dresses. How vivacious she appears as she dances late into the night!

The soldier who is patriotic, who is imbued with a close attachment to his buddies, who is proud of his outfit, will find few tasks too hard, will develop the endurance to keep going. Confidence in the outfit, faith in its leaders, the success of the venture, all influence fatigue or resistance to exhaustion. Outfits whose men lack confidence, who have little faith in their leaders, outfits which are retreating, have a disproportionately high percentage of nervous casualties. The prospect of victory is a tonic more invigorating than vitamins.

Medicinal Therapy—Situations arise when even well trained soldiers inspired by splendid morale reach a stage of exhaustion, yet military exigencies demand their further action. Thus, many measures have been tried in the hope of improving physical effort, or of delaying the onset of fatigue. Hellebrandt and Karpovich¹¹ have reviewed the use of special diets, sugar feeding, high vitamins, gelatin feeding, method of changing the acid balance (alkalies, phosphates, chlorides), beverages such as alcohol, coffee, tea. They state that there is no convincing proof that special hours of eating, excess sugar, extra vitamins, gelatin, or the acid-alkali group will improve performance of an aver-

age man Quoting from these authors, "Small doses of alcohol, beverages containing caffeine, amphetamine (benzedrine sulfate) or cocoa leaves all raise the level of physical performance in the course of prolonged effort by lessening the appreciation of fatigue Items to improve energy are usually dangerous but when the emergency is acute it may be wiser to resort to the use of substances which make men temporarily immune to fatigue than to abandon the exhausted"

The army uses *benzedrine sulfate* for such emergency purpose Circular Letter No 58 SGO¹² says, in effect "Benzedrine sulfate is a potent 'awakening' drug It stimulates dynamic energy, postponing the desire for sleep, and enables continuation of performance beyond the point at which physical fatigue would be overwhelming It will not improve the capacities of a rested person, and will cause sleeplessness if taken near bedtime Furthermore, it may produce palpitation, excitement, undue sense of tenseness and uneasiness In a special situation when it is important to alleviate fatigue and sleepiness benzedrine has proven highly useful It is administered after the appearance of fatigue, not as a preventive The dose is 5 mg for sleepiness, 10 mg for marked fatigue This dose, 10 mg, may be repeated if needed, at intervals of not over six hours for a total of three doses"

Aside from the use of benzedrine sulfate, we urge sufficient salt intake in the tropics Circular Letter No 119 SGO (July 1943)⁵ advocates gradual acclimatization, slowly increasing amounts of work, and the addition of free salt to the water intake

Treatment of Fatigue States with Features of a Neurosis—Despite the use of preventive measures, warfare brings exhaustion and exhaustion leads to the expression of hitherto controlled nervous reactions The rules of treatment are (1) early recognition (2) rest and sedation (3) psychotherapy

Braceland and Rome stress the need of removing a sailor from the area of duty if there are prodromal symptoms of mounting anxiety or excessive fatigue

The soldier who has been long in the front lines and whose loss of appetite, irritability, inefficiency and tremors, indicate advancing trouble, must be sent to the battalion aid station He must be removed from the sounds, dangers and hardships of front line fighting

At the battalion aid station or farther to the rear the soldier is given rest and sedation Major Hanson¹⁸ relied upon amytal sedation, first large enough to enforce deep sleep for some twenty-four hours, then sufficient to provide relaxation, but also to permit the soldier to attend to minor details Before the period of deep sleep, or soon afterwards, each soldier got a bath and a full diet with ample sugar and vitamins This period of rest reinvigorated tired muscles and broke the links of the chain of anxiety Braceland and Rome mention pentobarbital sodium, seconal and sodium amytal as the safest forms for intravenous use when it is advisable to induce deep sleep After an initial intra-

venous dose, such medication might be given orally Sargent¹⁴ stresses prompt approach "The urgency of treating with adequate deep sedation an acute neurosis in a good personality starting to break down is like an urgent operation for acute appendicitis This is followed by measures to improve that patient's weight loss by a modified insulin therapy (20 to 100 units of insulin at 7 00 A M The patient is not allowed to go into coma) "

Farrell and Appel state that recovery occurred in 60 to 80 of the cases arising in combat, with the patients returning to full combat duty provided they had been regarded as medical emergencies and properly treated Circular Letter No 176¹⁵ SGO entitled Early Recognition of Neuropsychiatric Conditions in the Combat Zone emphasizes selection, sedation and psychotherapy

Ross described the experience of soldiers in World War I "During the retreat from Mons the soldiers kept going for one week The army marched and fought and dug and marched and fought and dug At the end of this period they lay down and slept for thirty-six hours Refreshed by this sleep it took the battle of the Marne in its stride "

Hurst described soldiers as "tired almost to death," "staggering as though chloroformed," who after a few days' rest were young and fresh.

Psychotherapy—Refreshing rest, deep sleep and good food will be psychotherapeutic in their action Yet, in some instances, the fighting man needs some explanation, reassurance, relief of a feeling of guilt. Grinker and Spiegel¹⁶ provided such relief of emotional tension by encouraging the soldier to relieve his painful experiences under the influence of pentothal sodium Kubie suggests first rest and sedation, then physical measures and psychotherapy

For treatment of neurosis which has become established Kubie suggests primary measures consisting of controlled sleep plus physical restoration and psychotherapy in the form of superficial catharsis The first consideration is sleep, nourishment and some recreation, then the patient is given a chance to free himself of anxiety "Most emotionally disturbed patients try to hide their feelings When this effort fails, one sees all degrees of anxiety, with shaking, shivering, chattering, starting, dashing away to hide, sweating, vomiting, etc The patient may be lost in depression with suicidal tendencies or he may swing to wild and meaningless gaiety There may be an uncontrollable need to talk obsessively and endlessly about home and family about recent experiences, about the men who have been killed, about the conduct of officers, etc. Since human beings like to blame their troubles on superiors or on subordinates, pet hates and resentments will be heard frequently The patient should be guided to get release a feeling of guilt, relief of rage "

The average normal fighting man will respond favorably to food, sedation and psychotherapy Fatigue is reversible The

person can develop nervous symptoms from fatigue yet he will return quickly to normal when the situation is improved and when rest is provided. Many soldiers, however, do not improve sufficiently under such a program, indeed, symptoms remain chronic. What is the meaning of chronic fatigue and chronic neurotic reactions?

CHRONIC FATIGUE STATES AND NEUROSIS IN MILITARY LIFE

Though the fatigue state is for the most part a reversible process there are many examples of prolonged symptoms of exhaustion. Such conditions usually represent neuroses or some coexisting physical illness. Ross¹⁷ interprets the prolongation of illness from fatigue states as due to two causes: (1) fear of consequences of further exposure, and (2) gain to be derived from illness. It is Ross's opinion that these symptoms represent a defense against the possibility of further damage, and that if the soldier is assured that he will not be sent back to duty, the probability of recovery is increased. "Everyone wants to be well, but everyone is not prepared to accept in all the circumstances the consequences of being well."

Fatigue is not identical with neurosis even though at a certain point both may have similar symptoms. Fatigue is temporary, neurosis is likely to be prolonged, fatigue is the product of the situation, a neurosis is fundamentally related to the personality, even if the situation has induced active symptoms, fatigue is reversible, but neurosis is deep set.

What about the common ground between them? (1) Fatigue may induce neurotic symptoms—the tremors and anxiety constitute but a resemblance. All that glitters isn't gold, all who tremble aren't neurotics. (2) Fatigue may bring a true neurosis into evidence—activate it, as it were. Many a potential neurotic controls his symptoms by the effort of will power, by precautions, by activity. Busy and absorbed, he may produce effectively. A soldier may be struggling with the conflict between continuing to fight on or retreating. His sense of duty, his feeling for his buddies, his fear of censure will keep him in the fight. But once exhaustion has set in, this control is weakened, once he is hospitalized, the conflict is decided in favor of escape. Not that the soldier needs a conscious decision that this illness is a door to escape. Rather the mechanisms of self pity and introspection are awakened by the palpitation and the pain, fear of bodily failure, of serious disease is set in motion so that the soldier becomes a timid, trembling, tearful, and dependent patient. As long as he was going on and on, buoyed by the force of the group, stimulated by morale, he remained a good soldier—but once this link was broken he becomes a sick patient—all the latent fears, guilt, anxiety have come to the fore.

What about the conscious element, the factor of gain, of escape? Some believe that such gain, a conscious element is the effective force behind prolongation of symptoms. On the surface this appears so. Yet

one can only go as far as to say that the conscious factor reinforces the unconscious. The unconscious is basic, primary, develops out of the situation, the conscious is secondary. Yet its reinforcement adds much to the effectiveness of this force in maintaining invalidism.

The treatment of the true neurotic requires more time, a different setting, and usually, more involved techniques than mere rest and sedation. Such soldiers may have to be evacuated to the zone of the interior (the United States) away from the noise of bombers, away from fear of further exposure. Indeed, so powerful is this fear in some patients that they are relieved only when separated from service. Along with such evacuation comes intensive psychotherapy, analysis of the situation, free discussion, plus guidance, suggestion (see *The Mind of the Injured Man*¹⁸).

DIFFERENTIAL DIAGNOSIS BETWEEN COMBAT FATIGUE AND FATIGUE SECONDARY TO ILLNESS

As a rule, the fatigue states in combat are the result of the combined factors of exertion, deficiencies and fear. Yet often in civilian life and during training the patient emphasizes fatigue without obvious external factors. Physical disease can produce fatigue and nervous symptoms as well as the combat situation. Let us briefly discuss several common maladies.

Tuberculosis—In industry and less frequently in the armed forces (routine chest films) progressive fatigue ushers in pulmonary tuberculosis. Before cough, chest pains and obvious fever develop the patient may complain of tiredness, weakness, become apathetic or irritable and fail to carry out his duties.

Addison's Disease—Tuberculosis of the adrenals produces fatigue and this may be an important and prolonged symptom. A 38 year old soldier was inducted into the Army and sent to Florida for his basic training. During the earlier period of marching he complained of weakness. Later he "fell out at drill," stating he was too tired. He was at first suspected of being a "goldbrick." His fatigability grew worse. The soldier noticed that his skin was turning dark but was told that it came from the Florida sunshine. Weeks later he developed nausea and vomiting. He was therefore hospitalized and found to have pigmentation of the mucous membranes of his mouth, low blood pressure and chemical evidence pointing to Addison's disease.

Blood Dyscrasias and Pernicious Anemia—A lieutenant had difficulty in marching, his feet grew tired. Then he developed shortness of breath. Weeks later came numbness and tingling. During the earlier phase of this illness his appearance was one of good color and the true nature of the illness was not suspected. When the tingling was followed by unsteadiness in walking a neurological revealed evidence of combined sclerosis of the cord. Blood

and analysis of the gastric juice (achlorhydria) furnished the answer—pernicious anemia

Heart Disease—Fatigue on walking may be the prologue to the drama whose epilogue is decompensation. Leg weakness, then shortness of breath may be followed by angina or a true coronary attack. In the early phase fatigue may be the presenting symptom.

Malignancy—It is not rare for malignancy to start out as fatigue and then to give local evidence of its presence. A patient complained of weakness and nervousness, for which he was referred to a neuropsychiatric clinic. As he did not respond to psychotherapy, but instead lost weight, the psychiatrist requested a chest film (to rule out tuberculosis). The chest x-ray showed numerous coinlike rounded shadows which were interpreted as due to metastasis. Months later, the autopsy revealed that the primary source of this malignancy was a microscopic teratoma of the testes.

Other Diseases—Enough has already been mentioned so that we must keep in mind the possibility of inherent disease rather than the situation. In passing we can mention hyperthyroidism, undulant fever and hypertension as conditions to be considered. Then, also, endogenous depression may start out with weakness, leg tiredness, loss of appetite, and nervousness. Muscles are messengers of the mind and sometimes droopy posture and dragging legs will precede gloomy thoughts in the progress of symptoms of depression.

TREATMENT OF FATIGUE IN CIVILIAN AND INDUSTRIAL LIFE

Here we must first rule out physical disease, then evaluate the occupational situation. Is the fatigue due to excessive hours or boredom, is it due to physical exertion or unhappiness? In therapy we must remember the all-important influence of the mental attitude. It is good business as well as good medicine to furnish an incentive, to instill team spirit, to provide pleasant environment and remove as many industrial hazards as possible. Excessive cases of fatigue reflect upon management as well as the men fatigued.

CONCLUSION

Fatigue and exhaustion constitute a significant problem in war and in peace. In civilian industry fatigue is a symptom of excessive expenditure of energy without sufficient time for rest, results from physical disease, or is induced by a mental attitude of disinterest or dislike. Among fighting men these factors plus a succession of harrowing experiences, plus deficiencies of sleep and diet, and especially the influence of fear, lead to exhaustion states. As a rule such fatigue states are reversible. However, not all symptoms are the direct result of fatigue. Some arise as release phenomena, and these may persist especially if a marked potentiality to neurosis is awakened. The value to the ego of the escape from danger reinforces unconscious symp-

toms A careful differential diagnosis is essential Treatment along muscular, mental, and medicinal lines is indicated

PHYSICAL MEDICINE IN MEDICAL REHABILITATION

GORDON M. MARTIN, MD* AND FRANK H. KRUSEN, MD, I

Physical medicine has a vital role to play in the rehabilitation of individuals disabled by many nontraumatic or nonsurgical conditions. The vast majority of recent work and programs for rehabilitation has emphasized the rehabilitation of persons suffering from war wounds and industrial injuries. Less attention has been given to the less spectacular, but often just as disabling, medical conditions observed in civilian and nonwar years. Many common medical conditions observed in civilian and nonwar years, society is vitally interested in the rehabilitation of these individuals, whether physically disabled or partially disabled, producing at maximal capacity for the work of the group. However, in peacetime, when manpower is not in short supply, the problem of an individual disabled so that he cannot support himself is of less interest to society. A person disabled by chronic disease receives medical care, food and shelter. Often, the only palliative treatment is given with no attempt at a vigorous physical rehabilitation program aimed to prepare the disabled one for a self-supporting job, and little is done by industry to find a place for such an individual. In many states, compensation laws have discouraged and even prohibited the employment of physically handicapped persons.

The recent war years have shown that many partially disabled individuals can be fitted for a productive occupation suitable to the specific nature of their disablement. Industrial planning and placement boards are finding that job opportunities are leading the way in developing ways and means of decreasing periods of hospitalization and absence from active duty and military service (Grant,⁴ Rankin and Barton⁶). The aims of well-organized over-all medical rehabilitation programs must be to reduce convalescence to a minimum and to follow through with the treatment program of the individual until he attains his maximal functional capacity. These programs should continue to expand so that postwar rehabilitation and reconditioning programs will be available in all hospitals and clinics for private patients as well as patients on industrial and other medical insurance programs.

Physical medicine often can serve as a valuable part of the program

* Director of Physical Medicine, The University of Kansas Hospitals, Kansas City, Kansas

† Head of the Section on Physical Medicine, Mayo Clinic, Rochester, Minnesota

that aims to hasten the return of a disabled individual to his maximal functional capacity. Physical medical measures started early, prescribed carefully, and administered expertly have been found to shorten convalescence, reduce the period of hospitalization and minimize the expense to the patient and loss of hours from the job. The physical medical procedures should be carefully coordinated and integrated with the other types of treatment that are indicated for each individual.

PHYSICAL MEDICAL PROCEDURES

Principally, physical medical measures include the familiar triumvirate of heat, massage and therapeutic exercise. These may be used alone or in various combinations and in various forms to achieve the desired results. The fundamental physiologic reactions of the body to the various agents must be kept in mind if these agents are to be used properly and to the best advantage to help correct the abnormalities of the individual patient.

Heat—Heat, in general, can be used to increase circulation, relieve pain, increase local metabolism and relax tense muscles. The most effective means of applying heat locally to a region are (1) luminous heat lamps or bakers, (2) short wave diathermy, (3) hot paraffin, (4) hot soaks and (5) hot wet packs. General heating of the body is best accomplished by the hot tub bath (water temperature 100° to 106° F) or by use of a hot humid air cabinet.

Massage—Massage can be used either for sedative or stimulating effects. Stroking and kneading massage will improve venous and lymphatic flow and may be used to stretch intermuscular connective tissues. Friction massage can aid in stretching and loosening scar tissue and adhesions. Best results from massage are obtained when it is administered by an individual skilled in its application. Usually, the effects of massage are enhanced by preliminary application of heat for at least twenty or thirty minutes.

Exercise—Therapeutic exercise is undoubtedly the most important part of the physical medical phase of the rehabilitation and reconditioning programs for the majority of patients. The type and the amount of exercise will vary the condition being treated. Active exercise is used to improve muscle tone and muscle strength. Assistive exercise is used to increase range of motion. Passive exercise is used when it is desirable to prevent contractures, maintain muscle sense and aid circulation in a paralyzed extremity.

With therapeutic exercise established as the keynote of the physical medical phase of rehabilitation, it is obvious that complete cooperation of the patient is a primary requisite for successful carrying out of the program. The physicians, nurses, attendants and physical therapists are all responsible in helping the patient to realize his own responsibility for obtaining the maximal benefit most rapidly from the exercise program which is prescribed for him. A constantly changing program of

graduated exercises with definite goals to be attained must be prescribed and carefully supervised

Occupational Therapy—In addition to the physical therapeutic procedures just considered, occupational therapy provides another approach to the rehabilitation programs. Occupational therapy is a part of the physical medical program. It includes the use of prescribed work in the field of arts and crafts and recreational activities done by the patient as an aid in improving function of a part, or parts, as a diversional activity and morale builder, and, in some instances, as a part of a prevocational training program. By means of selected activities that interest the patient and are prescribed with definite aims in mind, the patient is further aided in feeling his own responsibility for attaining a maximal recovery. Unfortunately, at present there is a shortage of trained and competent occupational therapists. Physicians are not cognizant of the values, technics, indications and methods of prescribing occupational therapy for their patients. There is a lack of well-organized and accessible occupational therapy departments in most civilian and military hospitals. With more technicians being trained and the medical profession gradually learning about occupational therapy, it can be anticipated that the occupational therapy portion of physical medicine will, in the future, play a more prominent role in the rehabilitation programs for civilian, industrial and military patients.

MILITARY RECONDITIONING PROGRAMS

The Army general hospitals, and more especially the hospital services associated with the Army Air Force rehabilitation and reconditioning programs, have made extensive use of daily calisthenics beginning while the patient is still in bed (Rusk⁷). Generally two ten minute periods daily are set aside for the calisthenics. After the patient is able to pass an exercise tolerance test, described by Karpovich, Starr and Weiss,⁶ based on a return of pulse to a rate of below 100, the pulse being taken one minute after mounting a 20 inch step twelve times in thirty seconds, he is graduated to a more strenuous exercise program. In the more advanced classes the patient spends thirty to forty-five minutes twice daily in calisthenics, games and guerilla exercises that are conducted outdoors. The most advanced classes in the reconditioning programs include two forty-five minute periods of outdoor games, exercises and cross-country running and sprinting. This program has been found definitely to shorten the period of hospitalization and lower the incidence of relapses among patients suffering from respiratory infections including pneumonia.

PREVENTIVE PHYSICAL MEDICINE

Many years ago it was found that breathing exercises that were started soon after major surgical procedures lowered the incidence of

postoperative pneumonia These exercises are now used routinely in some form in most hospitals. Sometimes inhalation of carbon dioxide and oxygen is used as an added stimulus to the deep breathing. It is well known that to be of value the exercises must be done several times daily under the supervision of a nurse or attendant trained for this work.

The medical practitioner is still too frequently called to see patients suffering from *pulmonary embolism*. Several prophylactic measures have been used extensively. Dicumarol has proved to be of considerable value but requires careful observation and frequent determinations of the prothrombin time. Simple graduated exercises that are started at the same time as the breathing exercises have been found to be an aid in the prevention of pulmonary embolism. Wangenstein⁹ has emphasized the importance of constant active motion of the feet and toes during waking hours in obviating stagnation of venous blood in the legs. He expressed the opinion that this is an important factor in preventing thrombosis and embolism and in preparing the elderly surgical patient for becoming ambulant early.

A suggested group of simple exercises that can be started while the patient is still in bed could include some of the following:

- Exercise 1 Flexion and extension of toes. Repeat five to ten times.
- Exercise 2 Flexion and extension of ankle. Repeat five to ten times.
- Exercise 3 Circling of feet. (Circumduction with motion at ankle and midtarsal joints.) Repeat five to ten times.
- Exercise 4 Quadriceps setting. Tensing of quadriceps muscles in extension position of knee. Hold for a count of five. Repeat five to ten times.
- Exercise 5 Flexion of knee and hip, sliding foot on mattress toward the buttocks. Repeat five times.
- Exercise 6 Squeeze thighs together, then abduct them until feet are 12 inches (30.48 cm) apart. Repeat five times.
- Exercise 7 Gluteal setting. Squeeze buttocks together. Hold for count of five. Repeat five to ten times.
- Exercise 8 Deep breathing. Protrude abdomen (diaphragmatic breathing). Repeat five times.
- Exercise 9 Deep breathing. Raise thorax. Retract abdomen (thoracic respiration). Repeat five times.
- Exercise 10 Clench fist. Flex and extend elbow five to ten times.
- Exercise 11 From neck firm position. Draw arms forward to side of head. Then return to firmly retracted position against bed. Repeat five to ten times.
- Exercise 12 Flexion of neck. Chin toward thorax. Repeat five to ten times.

A minimum of five minutes twice daily should be spent in doing definite exercises. The exercises should be selected by the physician. Overfatigue must be avoided. A persistent elevated pulse rate follow-

ing exercises is an indication of overexercise. These or similar exercises are of value in aiding circulation by the action of the muscle on the veins. Muscular tone is improved and the commonly seen conditions of flabby, weak muscles and atrophy of disuse are minimized. A ward attendant, nurse or nurse's aid can be trained to supervise the patient in the prescribed exercises.

PHYSICAL MEDICINE APPLIED TO MEDICAL DISEASES

Arthritis—Rheumatoid arthritis involving peripheral joints, spinal column and the muscle is a commonly seen, chronic, disabling medical condition that affects both men and women during early adult life. Medical management should include a thorough search for, and eradication of, foci of infection, and the judicious use of salicylates, a trial of some type of arthrotropic or autogenous vaccine, adequate rest, well-balanced diet, vitamin supplements, a trial of large doses of vitamin D and possibly the intravenous use of gold salts.

Physical medical measures are used to improve peripheral circulation, relieve pain, lessen muscular atrophy, prevent deformity and improve articular function. The importance of daily use of physical measures cannot be overemphasized. Applications of heat for half an hour once or twice weekly is mentioned only to be condemned as a valueless procedure. Simple physical measures that the patient can use daily at home, in addition to what professional treatment he can afford or is available, should be included in the physical medical program.

Heat can be applied locally for thirty minutes daily by means of luminous heat lamp, melted paraffin (120° to 130° F), or short wave diathermy. Generalized bodily heating in a hot tub bath with a water temperature of 100° to 105° F for twenty minutes should be used two or three times weekly. This raises bodily temperature to about 100° to 101° F and is thought to aid the bodily defenses against the arthritis. Bodily metabolism is increased and the blood picture shows an increased leukocyte count.

Application of heat should be followed by a stroking and kneading massage especially to the muscular tissues around the involved joints. This aids in maintaining circulation through the muscles, stretches intramuscular connective tissue that may be involved in the arthritic process, and helps to prevent atrophy. Acutely inflamed joints should be avoided in the massage.

Exercise varies from minimal active and passive motion in acutely involved regions to vigorous active and assistive exercise in the chronic stages or in "burned out" arthritis with varying degrees of limitation of motion. Routine exercises can be supplemented by activities in occupational therapy that are used to improve function of joints as well as to provide mental diversion. When the arthritic process involves the spinal column, the exercise program also must include postural training as well as intensive exercises to maintain or improve

expansion of the thorax Here again, as with the use of heat, the prescribed exercises should become a part of the patient's daily life, they should be done regularly and as often as prescribed by the physician, and done with the same regularity as the individual takes internal medications

Poliomyelitis—The physical medical management of poliomyelitis probably results in the best final functional results of any type of treatment that is used During the acute stage with painful, tender muscles, hot packs tend to produce considerable symptomatic relief The patient is positioned in bed with a firm mattress and foot board in such a way as to prevent overstretching of weakened muscles and lessen the tendency to deformities Passive exercise is started early Careful manual muscle re-education technics are used to obtain maximal functional efficiency of all the muscles that are able to contract The purpose of the careful muscle re-education is to encourage the use of weak muscles and discourage the use of stronger muscles which the patient naturally tends to substitute to carry out an action The patient can be taught to relax an antagonist muscle whose contraction tends to interfere with the action of a weakened agonist or prime mover Frequent observation during the recovery period, which may last many months, will guide the patient in the proper use of his muscles as function returns Deformities can be observed in their incipient stage and often can be prevented from resulting in structural changes

Vascular Diseases—Thrombo-angitis obliterans is a chronic disabling disease that usually occurs during the most active and productive years of a man's life Here again, as in the case of arthritis, physical medicine serves as an adjunct to medical and surgical procedures that make up a successful treatment program In the early stages, considerable symptomatic relief may be obtained by use of a Sanders oscillating bed for several hours daily This may be of value in relieving pain and improving circulation by means of passive vascular exercise Allen and Kvale¹ have pointed out that it never has been definitely proved whether or not the Buerger-Allen postural exercises improve peripheral circulation However, theoretically, the physiologic effects should be similar to those obtained by the use of the oscillating bed

In cases of thrombo-angitis obliterans, heat, which is used for its vasodilating effect should be applied to a distant part Brown and Allen² have devised an electrically heated sleeve that can be left on an arm for many hours, and it has been shown that this application of heat will result in vasodilatation of the peripheral vessels in the other extremities Bennet, Hines, and Krusen² have shown that short wave diathermy applied under the lumbosacral region results in a vasodilatation in the lower extremities De Takáts and Miller³ have found that use of the ordinary luminous heat baker over the abdomen and upper thighs is a simple, safe and effective method of applying heat to cause vasodilatation in the lower extremities Heat applied locally to the in-

volved part may increase pain and hasten the tendency to destruction of tissue and gangrene by increasing metabolism of the part with an inadequate blood supply. Contrast baths and the application of cold should be avoided.

Tuberculosis—The long period of convalescence can be made more tolerable for the patient if well-planned occupational therapy activities are arranged. Productive activity is the best morale builder. Activities are available that require a minimum of physical exertion and yet provide excellent diversion so that a more relaxed type of rest program is attained. Ultraviolet light treatment or heliotherapy for patients suffering with tuberculosis of joints and certain patients with pulmonary lesions probably is not used enough in this country. This form of treatment forms an important part of the treatment programs for tuberculosis as outlined by Rollier and other European physicians.

Cerebral Palsy—It is becoming more generally apparent that much can be done for the many patients with spastic paralysis who have a nearly normal or superior mentality. Physical medical procedures carried out for a period of many months or years often will enable these patients to become much more efficient with improved muscular control and coordination. Certain surgical procedures are often indicated as part of the over-all treatment program.

Heat in the form of heat lamps, warm baths, or warm pools and, at times, combined with a slow stroking massage for its sedative and relaxing effects will be of benefit in reducing the tightness in the hypertonic muscles. Specialized exercise again is probably the most important single physical medical measure. A certain amount of voluntary relaxation can be learned. Rhythmic exercises, beginning with gross movements, are mastered first. Later, finer movements are learned. Progress will be slow. It may even be hindered by proceeding too fast. More special schools for early treatment of these patients in the pre-school years are needed. More technicians especially interested and trained in helping these patients are needed.

CONCLUSIONS

Physical medicine can play a vital role in the rehabilitation and reconditioning programs that should be made available to all patients suffering from disabling medical conditions. Exercise reconditioning programs started while the patient is still in bed will shorten hospitalization and convalescence in cases of respiratory infections, including pneumonia. More prolonged rehabilitation programs in which physical medicine takes a prominent part are being planned for patients suffering from the various types of arthritis, tuberculosis, poliomyelitis and cerebral palsy. The Baruch Committee with an active subcommittee on rehabilitation is doing an important work in encouraging and coordinating the various phases of physical medicine with both the industrial and military rehabilitation and reconditioning programs. NUTRITION IN REHABILITATION

TOM D SPIES, M D , F A C P *

MAN's existence is literally a struggle for food. From conception to death he is beset with impediments to good nutrition. Throughout life many conditions may arise to prevent his having an adequate intake of essential nutrients, and he is subject to many diseases that interfere with their absorption or utilization. When, for any reason, deprivation of nutrients occurs, protective mechanisms within the body serve to compensate for a depletion of nutrients, but if the deprivation becomes protracted, these mechanisms eventually fail and signs of bodily derangement begin to appear. Symptoms, such as pellagrous glossitis or dermatitis, beriberi neuritis or beriberi heart, cheilosis or the ocular symptoms of riboflavin deficiency, scorbutic hemorrhages or gingivitis, may appear singly or in combination. They are, however, but prominent presenting symptoms of what we have come to call nutritive failure †. In order to rehabilitate the person with nutritive failure,

University of Cincinnati Studies in Nutrition at the Hillman Hospital, Birmingham, Alabama. From the Department of Internal Medicine, University of Cincinnati.

The tremendously heavy expenses of the general nutrition study have been borne by grants from a number of philanthropic persons, foundations and commercial concerns, without which this study could not have been made. The necessary expense of frequent observations of these patients in their homes and in the clinic has been defrayed by grants from the John and Mary Markle Foundation and from Lever Brothers.

We are indebted especially to Mrs. Jane M. Mann for most of the nursing care and to Mrs. Merle S. Babb and Mrs. Stephen Dill, social workers, for the follow-up work in the homes of the patients.

*Associate Professor of Medicine, University of Cincinnati, Cincinnati, Ohio, Director, Nutrition Clinic, Hillman Hospital, Birmingham, Alabama.

†The term "nutritive failure" perhaps means different things to different physicians. It is used in our clinic to describe a variable clinical picture and does not have a specific physiologic connotation. It does not indicate why the nutrition has failed but simply that it has failed.

Our work has convinced us that many times the physician cannot determine at once the physiologic basis of the nutritional insufficiency, and by the use of this term he can describe briefly the clinical picture without knowing the precise causation. The term has become so commonly entrenched in our clinical usage that it does not seem wise for us to restrict it or to change it.

For the sake of clarity, the various disturbances and mechanisms which create a picture of nutritive failure we often describe separately. We can see pellagrous dermatitis or glossitis, beriberi neuritis or beriberi heart disease, scorbutic hemorrhages or gingivitis, cheilosis or the ocular symptoms of riboflavin deficiency as present symptoms arising as a response of the body to a long-continued deprivation of certain nutrients in food. Hence, nutritive failure is a more inclusive term than pellagra, beriberi, scurvy or riboflavin deficiency in that it connotes varying degrees of mixed deficiencies operating simultaneously.

we must remove, whenever possible, the causative factors and apply therapy that will not only correct the specific deficiency disease but will also restore completely the patient's nutritional status

Primary malnutrition occurs as a result of failure over a period of time to eat a diet which is adequate in all nutritive respects. Secondary malnutrition occurs when any disease or diseases interfere with the orderly processes of nutrition. It is not sufficient that a person have access to adequate food. It must be properly prepared and sufficient amounts of all the necessary constituents must be ingested and absorbed before the body can utilize them. Any illness may interfere with the natural and powerful instinct which urges us to obtain food. Claude Bernard has emphasized the fact that "all vital mechanisms, however varied they may be, have but one object, that of preserving constant the conditions of life in the internal environment." Normal nutrition constitutes the *sine qua non* of this mechanism. Without an intake of essential nutrients sufficient to meet the body's needs, all stabilizing forces eventually fail. Diseases may interfere with the proper assimilation and become an effective barrier between food and the health of the body. Then nutritional disaster comes.

During the past two decades numerous surveys of the diets of various population groups in the United States have shown that the nutritional quality of their diets left much to be desired. Little was done about it, however, until the tremendous withdrawal of young men from the farms and factories into the armed forces and the enormous production of material for war required the employment of thousands of new workers. This urgent need for manpower stimulated interest in the health and welfare of workers. Realizing the importance of nutrition in maintaining health, many physicians, nutritionists and nurses directed their efforts toward improving the feeding of industrial workers and in educating the public as to the rudiments of a satisfactory diet. The results are gratifying, but there is still much to be done. Even if it should come to pass that our knowledge of nutrition be applied in a fully effective manner toward maintaining health, the fullest benefits of this knowledge cannot be realized until it is applied toward persons who are now unable to work because they are debilitated by nutritive failure. Up to this time, however, comparatively little has been done on this problem. It is true that food has always held a place in rehabilitation programs, but its use has often been so haphazard that it was not fully effective. The vigorous young science of nutrition is constantly bringing new and valuable information. Our studies have led us to believe that the scientific and judicious application of this information can rehabilitate many persons.^{1 2 3}

We are convinced that there is in some areas a vast resource of potential manpower among persons debilitated by malnutrition. We believe that not only are there countless persons debilitated solely by malnutrition, but that in many persons debilitated by other diseases

the nutritional status is so impaired that it is retarding their recovery.⁴ Many of these persons have been incapable of any productive effort for years, and often they are dependent upon their families or upon social agencies. The loss of manpower attributable directly or indirectly to malnutrition is far greater than it need be. This is partly due to the fact that few physicians realize the number, the variety and the seriousness of the nutritional disorders to which man is subject or the care and skill necessary to keep human beings well nourished so that they can maintain their place in the intensive production that prevails in this country. It is due also to the fact that many physicians fail to recognize nutritional deficiencies, to apply proper therapy, or to continue treatment until the patient is fully restored to health.

Studies of nutritive failure in Ohio and in Alabama over the past fourteen years have shown us that it frequently follows diseases of the alimentary tract, surgical operations of various kinds, infections, pregnancy and lactation, neoplasm, endocrine disorders, congestive heart failure, long continued deep x-ray therapy, severe anemia and hemorrhages, diabetes, allergic states, and similar disorders. Pregnancy and lactation are very influential in precipitating the clinical manifestations of deficiency diseases where malnutrition is endemic. Likewise, we have found that in a person whose nutrition is such that little or no margin of safety exists, surgical operations and long-continued illnesses are much more of a burden than they are in well nourished persons.

From my fourteen years of study I have developed a concept of the relationship of organic disease to secondary malnutrition: the individual who has had a satisfactory diet prior to illness develops secondary nutritive failure only when the illness is severe or prolonged, whereas a person who has been on a deficient diet for many years will fall into nutritive failure with the most trivial illness. Accordingly, the degree of secondary nutritive failure is determined by the initial state of nutrition and the degree of extraneous organic disease.

It is apparent from these many years of work that nutritive failure exists first in a prodromal stage. The final disturbances occur after biochemical changes interfere with cellular function. Long after the biochemical changes first appear, they may become translated into morphological lesions which we will eventually be able to recognize as the fingerprint of the deficiency diseases or syndrome. Our studies⁴ indicate that secondary malnutrition of a serious nature is more prevalent than any survey would indicate at any given time.

The practicing physician has been overwhelmed by an avalanche of technical material far too great for him to crystallize and use in an orderly fashion. This has resulted in the treatment of the acute stage of nutritive failure for a short time, but the recuperative stage has been neglected. The result has been that the patient has drifted through an unnecessarily long period of convalescence. Needless relapses have been far too common. The purpose of presenting the following facts

is to stress the need of accurate diagnosis and proper therapy throughout convalescence as necessities in rehabilitation following nutritive failure.

DIAGNOSIS

Of great importance in making a diagnosis and instituting therapy is information in regard to the patient's previous and present dietary, his economic status (which almost invariably affects the quality of his diet), all the other predisposing factors which might have precipitated his nutritive breakdown, and his symptoms and the time of their onset. This can best be done by the conservative interpretation of data obtained from a careful medical and dietary history and a complete physical examination. In collecting such data, no outline is satisfactory in every detail for every patient. Nevertheless, we have found certain forms helpful. These forms are described in detail in a recent publication.³

We suspect nutritional deficiencies in the following groups

1 *Those who are indigent* Such persons seldom have enough money to buy all the foods needed for an adequate diet. Many of them have subsisted for years on high carbohydrate foods, such as bread, cereals, dried vegetables, and sugars—foods which are relatively inexpensive. Their diets usually contain far too little milk, dairy products, meat protein, green vegetables or fruit. Consequently their diets are low in protein, minerals and vitamins. Many such persons gradually lose their appetites and voluntarily reduce their food intake until even their calorie intake is inadequate.

2 *Persons with histories of erroneous dietary habits or food idiosyncrasies* Such persons frequently eat unbalanced diets deficient in some of the essential nutrients.

3 *Persons with organic diseases or infections which may interfere with the ingestion or utilization of food* Another too frequent cause of nutritive failure of a patient in this group is the therapeutic diet sometimes prescribed by the physician for the treatment of some specific disease. Although all therapeutic diets are not necessarily inadequate, we frequently see patients who develop nutritional deficiencies as the result of eating a diet prescribed for therapeutic purposes. We suggest that the physician carefully check the therapeutic diet he prescribes for each individual to see that it supplies the foods necessary for an adequate diet. If the restrictions are such that the foods permitted do not supply adequate amounts of the essential nutrients the diet should be supplemented with the nutrients in which it is deficient.

4 *Pregnant and lactating women and persons whose physical exercise is increased* In such persons the requirement of all the nutrients is increased and unless their intake of nutrients is likewise increased their nutritional status is almost certain to become impaired. Too often the food intake is increased by adding additional calories in the form of fat and carbohydrates and the diet becomes unbalanced. It is essential to increase the supply of all the essential nutrients, and if this cannot be done by food alone it should be done by supplementing the diet with nutrients in the form of synthetic substances or concentrates.

5 *Persons who are chronically addicted to alcohol* Such persons often substitute alcohol, which contains no nutrients other than calories, for food. If however a liberal, well-balanced diet is eaten deficiency diseases are not likely to develop even when large amounts of alcohol are ingested.⁴

In a patient in any of these groups, we suspect a developing nutritional deficiency. The early symptoms of nutritive failure include loss of weight and strength, headaches, dizziness, burning sensations of the skin in various parts of the body, roughness and dryness of the skin, burning of the eyes, blurring of the vision, lacrimation, photophobia and night blindness, burning and cramping of the stomach, burning of the tongue and lips, redness and swelling and ulceration of the tongue and mucous membranes of the mouth, increased salivation, diarrhea, burning and cramping of the feet and legs, central nervous system disturbances, which include insomnia, general nervousness, loss of memory, apprehension and hypersensitive emotional reactions.

The diagnosis of vitamin deficiency diseases is made only in the presence of one or more diagnostic lesions. Pellagra, for example, is diagnosed only in the presence of characteristic oral mucous membrane lesions or dermal lesions, beriberi only in the presence of nutritional neuritis, riboflavin deficiency only in the presence of cheilosis or typical ocular lesions, scurvy only in the presence of characteristic gum lesions or perifollicular hemorrhages.

While we perform many *laboratory tests* in our clinic, they are not, in themselves, diagnostic of deficiency states. The results of such tests, however, when correlated with the information gained from the physical examination and the medical and dietary history, are often helpful in making a diagnosis. Although they are not always practical for use by the practicing physician, facilities for some of them might be available to some physicians. We have gained useful information from various laboratory tests which include the determination of the amount of hemoglobin, red blood cells, and the packed cell volume, serum protein and albumin determinations by the Kjeldahl technic, ascorbic acid determination on plasma⁶, slit lamp and biomicroscopic examinations of the capillaries in the conjunctiva and cornea, the B.E.S. test,⁷ the colorimetric method of detecting small quantities of abnormal pigments in the urine, urinary excretion tests for thiamine⁸ and niacin⁹, determinations of riboflavin¹⁰ and pantothenic acid¹¹ in the blood, microscopic examination for Vincent's organisms, staphylococci and streptococci in smears taken from mucous membrane lesions in the mouth, tests for hydrochloric acid, pepsinogen, and rennin in the gastric contents before and after histamine injection, and in some special cases we determined the presence or absence of the intrinsic factor of Castle.

Sufficient stress cannot be placed on the importance of searching for *mixed* deficiencies. Too often a diagnosis of a single deficiency is made, and therapy is directed toward the restoration of a single nutrient. Deficiencies rarely, if ever, exist singly. The correction of a single predominating deficiency may give temporary relief, but it will not restore completely the patient's health nor maintain him in an optimum state of nutrition. Such a procedure may, moreover, precipitate signs & symptoms of other deficiencies.

TREATMENT

The dietary treatment of patients with deficiency disease, whether they are in bed at home or in the hospital or whether they remain ambulatory, is based on the principles of good nutrition. The diet must contain adequate amounts of protein, calories, minerals and vitamins. It must be remembered, however, that the nutritional stores of the body are likely to be severely depleted. Accordingly, the diet must supply much more than normal amounts of the essential nutrients. Therefore, the recommended diet should supply 3000 to 4000 calories, 120 to 150 gm of protein, and liberal amounts of minerals and vitamins. The type of food prescribed and the form in which it is given depend entirely upon the ability of the patient to ingest and retain food. Frequently the patient's desire for food is absent, and he has to be persuaded to eat. In the severely ill patient, the mouth and tongue may be so sensitive that only soft or liquid foods can be tolerated, and highly seasoned or acid foods must be avoided. In some instances only a small amount of food can be taken at one time, and it is necessary to give small feedings at frequent intervals. As the patient improves, semisolid and solid foods can be given. In all cases with diarrhea, solid foods should be added as soon as possible. In the dietary treatment of deficiency diseases, we have found the following diets* useful.

4000 CALORIE LIQUID DIET

Suggested Hourly Feeding

- 7 A.M. Cereal gruel—1 serving (see recipe)
Milk—1 glass
- 8 A.M. Eggnog—1 glass (see recipe)
- 9 A.M. Eggnog—1 glass
- 10 A.M. Ice cream
Fruit juice with egg (see recipe)
- 11 A.M. Eggnog—1 glass
- 12 noon Cream soup—1 serving (see recipe)
Milk—1 glass
- 1 P.M. Eggnog—1 glass
- 2 P.M. Ice cream—1 serving
- 3 P.M. Eggnog—1 glass
- 4 P.M. Ice cream—1 serving
- 5 P.M. Cereal gruel—1 serving
- 6 P.M. Eggnog—1 glass
- 7 P.M. Cream soup—1 serving
Ice cream—1 serving

*These diets were worked out by Miss Jean M. Grant, dietitian, Nutritional Clinic, Hillman Hospital, Birmingham, Alabama.

4000 CALORIE "SOFT-SOLID" DIET

Suggested Meals

Breakfast, 8 A.M. Fruit juice—1 glass
Cooked cereal—1 serving ($\frac{1}{2}$ cup)
Cream— $\frac{1}{4}$ cup
Sugar—2 teaspoons
Soft cooked eggs—2
Milk toast—Toast, 1 slice
Milk, $\frac{1}{2}$ cup
Butter, 1 square (2 teaspoons)
Milk—1 glass
Coffee—if desired

10 A.M.	Eggnog—1 glass (see recipe) Ice cream or puddings—1 serving
Lunch, 12 noon	Cream soup—1 serving (see recipe) Soft cooked eggs—2 Milk toast—Bread, 1 slice Milk, $\frac{1}{2}$ cup Butter 2 teaspoons Mashed potato or boiled rice—1 serving ($\frac{1}{2}$ cup) Butter—1 pat (2 teaspoons) Ice cream or pudding—1 serving Milk—1 glass
2 P.M.	Eggnog—1 glass
4 P.M.	Eggnog—1 glass
Supper, 6 P.M.	Cream soup—1 serving Cooked cereal— $\frac{1}{2}$ cup Cream— $\frac{1}{4}$ cup Sugar—2 teaspoons Soft cooked eggs—2 Ice cream or pudding—1 serving Milk—1 glass
8 P.M.	Eggnog—1 glass

Note Cup = standard 8-ounce measuring cup
Glass = 8-ounce water glass

Approximate Food Value of Diet

Proteins	147 gm.
Total calories	4153

4000 CALORIE "SOLID" DIET

Suggested Meals and Between Meal Feedings

Breakfast, 8 A.M.	Fruit juice—1 glass Cereal—large serving Eggs—2 Bacon or ham—if desired Toast—2 slices Butter—2 pats Cream— $\frac{1}{2}$ cup (for cereal and coffee) Milk—1 glass Coffee—if desired
10 A.M.	Eggnog—1 glass (see recipe)
Dinner	Lean meat, chicken or fish—3 ounces Potato macaroni spaghetti noodles, or dried beans or peas (1 serving) Vegetable—large serving (green or yellow vegetable—may be cooked or used as salad. If cooked add 1 square of butter. If used as salad, add 1 tablespoon mayonnaise) Bread—2 slices Butter—2 pats Dessert—1 serving Milk—1 glass

2 P.M.	Eggnog—1 glass
4 P.M.	Eggnog—1 glass
Supper, 6 P.M.	Lean meat, chicken or fish—3 ounces Potato, macaroni, spaghetti, noodles, or dried beans or peas (1 serving) Vegetable—large serving (green or yellow vegetable—may be cooked or used as salad. If cooked, add 1 square of butter. If used as salad, add 1 tablespoon mayonnaise) Bread—2 slices Butter—2 pats Dessert—1 serving Milk—1 glass
8 P.M.	Eggnog—1 glass

Approximate Food Value of Diet

Protein	148 gm
Total calories	3980

RECIPES

<i>Eggnog</i>	6 eggs, 4 tablespoons sugar, 6 cups milk. Beat eggs. Add sugar. Add milk. Beat mixture well. Chocolate syrup or vanilla may be added if desired. <i>Makes 4 servings</i>
<i>Cereal Gruel</i>	$\frac{1}{2}$ cup of any kind of cooked cereal thinned to desired consistency with milk and served with $\frac{1}{4}$ cup of cream and with sugar if desired
<i>Cream Soup</i>	$\frac{1}{4}$ cup strained vegetable or canned tomato, pea, spinach or asparagus soup. Add $\frac{1}{2}$ cup cream
<i>Fruit Juice with Egg</i>	Beat 1 egg well. Add 1 cup fruit juice. Add sugar as desired

It should be pointed out, however, that in certain diseases, such as allergy, diabetes and gastric ulcer, which necessitate restricting the kind or amount of food, these diets would not be suitable. Such cases require individual diet therapy, a detailed discussion of which is beyond the limits of this paper.

Important as food is in the treatment of nutritive failure, therapy should not be restricted to food alone. Deprivation of nutrients usually has existed for years, and the average patient cannot eat enough food to supply the amount of these nutrients necessary to restore his health. Accordingly, supplements of the nutrients in which the diet is deficient are given. Until synthetic vitamins become available, dried brewers' yeast powder, wheat germ, liver concentrates and citrus fruit were given in treating deficiencies of the water-soluble vitamins. As valuable as these substances were, and still are, there are times when synthetic substances are life-saving.

It has been our experience that severe deficiencies of the water-

soluble vitamins are much more common than those of the fat-soluble group (A and D). Moreover, although symptoms of one deficiency may predominate, other deficiencies are almost certain to exist. Accordingly, in treating the clinical syndromes of *beriberi*, *pellagra*, *riboflavin deficiency* and *scurvy*, a basic formula is prescribed once to three times daily which contains 10 mg of thiamine, 50 mg niacinamide, 5 mg riboflavin, and 75 mg ascorbic acid. When the symptoms of one deficiency predominate, as they usually do, more of the vitamins specific for the predominating deficiency is added to the basic formula. In the case of *beriberi*, 10 mg thiamine is added daily, in *riboflavin deficiency* 5 mg riboflavin twice a day, in *scurvy* 100 mg ascorbic acid three times a day, and in mild *pellagra* 50 mg niacinamide three times a day. If the *pellagra* is severe, the patient is given 150 mg of niacinamide daily in addition to the basic formula. In most cases oral administration of vitamins is the method of choice, but if the patient is moribund, it may be necessary to give them by the parenteral route. When large amounts of *d*-glucose are injected daily, the inclusion of 20 mg of niacinamide, 5 mg of riboflavin, and 5 mg of thiamine is recommended. In a few instances of severe vitamin C deficiency, we have injected 500 mg of ascorbic acid in isotonic solution of sodium chloride.

Dried brewers' yeast powder, liver extract, wheat germ and rice polishings are excellent therapeutic agents in the treatment of *B complex deficiencies*. In addition to supplying all the known factors of the B complex and probably some as yet unknown, they contain significant amounts of protein and other essential nutrients. The amount of these materials administered depends upon the severity of the disease. We usually give daily from 4 to 6 ounces of dried brewers' yeast powder or oral liver extract, from three to four doses of 20 cc of parenteral liver extract, or from 150 to 300 gm of wheat germ. The flavor of these materials, which some patients find so disagreeable that they will take them only under protest, can be masked somewhat by combining them with milk or tomato juice or by mixing them with water and adding tomato catsup.

In *vitamin A deficiency*, the diet of the adult is supplemented with 50,000 units of vitamin A daily for at least two months. The clinical response to vitamin A deficiency is slow, and it may be necessary to continue treatment over a long period of time.

In treating persons debilitated solely by nutritive failure, we do not regard treatment as satisfactory until the patient has gained in strength, until his weight has returned to normal, and until he is able to return to work and to continue to work regularly.

Following the application of these methods of diagnosis and therapy we have seen several hundred persons with nutritive failure completely rehabilitated. Prior to treatment many of them had been unable to work for years and were entirely dependent upon their families or

upon social agencies. They are now contributing their efforts in various fields of production. The type of work in which 800 persons who were debilitated solely by nutritional deficiencies are now engaged is illustrated in the following table:

Armed Forces	41
Agriculture	101
Domestic service	359
Industry	299

The 800 persons in this group, as do most of the patients in our clinic, developed nutritive failure solely as the result of an inadequate food intake. We have treated many patients, however, in whom nutritive failure was secondary to organic disease and a few whose chronic addiction to alcohol has led them to substitute alcohol for food. When organic disease or addiction to alcohol is the predisposing cause of a nutritive breakdown, rehabilitation is much more difficult than when an inadequate food intake is the sole cause. In some cases it is impossible. Nevertheless, many of these persons can be rehabilitated and the health of others can be improved to such an extent that they can lead more comfortable and useful lives than they did prior to treatment. In persons with deficiency diseases that are secondary to organic disease, this can best be accomplished by combining nutritive therapy and treatment of the disease that predisposed to nutritive failure. Successful treatment of the patient chronically addicted to alcohol is based on adequate nutritive therapy, education of the patient in regard to the importance of eating an adequate diet at all times, and continued observation of the patient so that therapy can be instituted immediately should any symptoms of nutritive failure reappear.

I wish to stress that our work in the field of rehabilitation has been concerned wholly with making it possible for the man to perform work. We have made no attempt to fit the man to the job nor the job to the man. We have given no physical training nor have we used any tests for scoring performance. Our only concern has been in restoring the patient's nutritional status and health.

SUMMARY

Few physicians realize the meticulous clinical study needed before a diagnosis of deficiency disease is justified. The science of nutrition has advanced so rapidly that the practicing physician naturally wonders what he can include as valid in his day-to-day practice of medicine. By the application of the methods of diagnosis and therapy described in this paper we feel certain that he will be gratified by seeing many patients fully recover their health and return to work.

Proper nutritive therapy throughout the acute stage of illness and convalescence completely rehabilitates many persons debilitated by

THE PROBLEM OF REHABILITATION IN CIVILIAN MEDICAL PRACTICE

WILLIAM BENJAM SNOW, M D *

DEFINITION AND AIMS

THE word "rehabilitation" has many applications. In these wearisome war years minds turn to postwar rehabilitation with reference to national and political changes worldwide in scope, social changes predicated on rebuilding a desolated world, economists plans for rehabilitation of finances, and policies formulated for a better world based upon the greatest number of "freedoms" possible consistent with maintenance of law, order and future happiness as far into the future as our imagination can extend.

We hope for all of these, and better minds than medical ones can shape such destinies. The medical profession and allied agencies are faced today with certain problems which the war has brought immediately into focus. Many in the medical profession are suddenly realizing that a new field of usefulness has opened up, namely the rehabilitation of handicapped individuals. Processes of rehabilitation are being discussed and furthered as never before. More minds devoted to the problem should probably bring more complete and satisfactory results. On the other hand, war and its associated emotional outpourings bring with them a tremendous amount of loose, careless thinking which avails little of real usefulness. There have been some new problems in rehabilitation which have come out of this war, but the greatest amount of rehabilitation needs are not new, nor are they peculiar to war. Processes of rehabilitation are a constant need wherever men work, play and live in and about the complications of machine-operated society.

"Rehabilitation is the restoration of the handicapped to the fullest physical, mental, social, vocational and economic usefulness of which they are capable."¹ Unfortunately, the aims of this utopian definition exceed the accomplishment fulfilled in the lives of a large percentage of normal individuals. At any one moment in any individual's lifetime he represents a very complicated collection of experiences, impressions, emotions, aims and ambitions. He enjoys a degree of health dependent on his hereditary endowments, health habits, education, experiences and the physical impressions of past illness. Psychically he can be identified in one or more groupings, as phlegmatic hyper-

Director of Physical and Occupational Therapy Columbia Presbyterian Medical Center Associate in Medicine, College of Physicians and Surgeons, Columbia University New York City

tensive, calloused or sensitive, emotionally stable or unstable, kind or unkind, generous or greedy, slothful or alive, ambitious or lacking in incentive, to mention a few. With these thoughts in mind, rehabilitation of an individual who has been dislocated from the normal trend of his life through ill health, disease or injury, must be considered as no simple problem. As physicians, we are interested in physical and mental restoration of this individual. His problem is the problem of rehabilitating John Jones, a man, with a past and a future different from that of any other individual in the world.

Actually, many individuals in civilian life who are subjects for rehabilitation never did amount to very much. When we try to fit the utopian definition of rehabilitation to these figures we attempt an impossibility. On the other hand, the fact that an individual has not made the most of his opportunities does not mean that he may not be shocked from indifference into sober reality, and that his disability may become his saving grace and represent the first move toward his taking a useful place in society.

The psychology underlying rehabilitation of the handicapped represents the crux to the problem. Unless a proper psychological reaction is obtainable, rehabilitation cannot proceed. Those concerned with rehabilitation must represent a united front which goes to work on the subject with tact, judgment, understanding and patience all combined in such a manner as to preserve the dignity and self-respect of the individual being rehabilitated. This is America. As such our medical applications are best when carried out democratically.

THE REHABILITATION PROBLEM IN A CIVILIAN HOSPITAL OR MEDICAL CENTER

It Differs from the Military Problem of Rehabilitation —I would like to discuss certain thoughts covering rehabilitation in a hospital or medical center. The thoughts will not be directed toward war injuries for the reasons already set down. Likewise, the rehabilitation program which has to be met in civilian life is far more complicated. It includes many classes of individuals and medical conditions which by their very nature never would be found in a military set-up. Hereditary handicaps, certain childhood diseases and orthopedic deformities are a few of these. Likewise, the doctor-patient relationships in the armed forces and in civilian life digress widely. Certain compulsions exist in military medicine which are nonexistent in civilian practice. Free choice of physician by the patient and the normal competition existing in civilian hospitals and private practice likewise affect rehabilitation. Possibility for independent action in treatment free from official directive, makes for the more independent handling of rehabilitation in civilian practice than is possible in the Army. In the latter, exigencies may demand invocation of certain decisions which mitigate against the individual in a system where "the greatest good for the greatest number" and "fighting manpower" are the immediate aims of rehabilitation. The

further back from the front lines the patient gets, the nearer will these two attitudes in rehabilitation converge

Peace Will Bring Changes—In the postwar period, many veterans with disabilities will seek medical assistance in other than government hospitals for several reasons. Physicians who have been exposed to the problems of rehabilitation will return with advanced ideas on rehabilitation and seek an outlet for these ideas in the civilian hospitals to which they will return. Thus awakened medical interest in rehabilitation will require the introduction of considerable changes in hospital practice. Civilian hospitals should investigate the problem of rehabilitation before it is forced upon them too late. The trend is already here.

Convalescent Care—a Weak Link—Rehabilitation is only a step removed from convalescence. Convalescent care is probably the weakest link in the chain of medical service. Rehabilitation begins with the making of a diagnosis. Convalescence follows after the first steps of treatment have been taken. Every patient put to bed will either convalesce and be rehabilitated, become chronically debilitated, or die. When the diagnosis is established and the gravity of the patient's condition is weighed, the physician has the right to an opinion as to what the ultimate outcome may be. If the patient's prognosis is hopeless, certain obligations exist. If the condition is to become chronic, some idea certainly exists in the physician's mind as to what is the best long-range program to pursue to extend the patient's life with the greatest degree of comfort, happiness, independence and freedom from handicap.

If the diagnosis is suggestive of recovery to somewhat the patient's original state, depending on the illness and its expected duration, certain prophylactic, curative and convalescent procedures will be indicated.

The Harmful Effects of Prolonged Bed Rest—Prolonged bed rest, if required in the treatment of an illness, carries with it certain physiologic alterations associated with inactivity.² Medical men have been fully aware of these tendencies but in a vast number of instances we have done nothing about it. For years we have hurried old folks out of bed to prevent circulatory stasis and muscular atrophy from occurring, and have permitted younger persons to be victims of the same complications. There is a distinct progressive upsurge in cutting down bed rest today. Internal fixation in orthopedic and fracture practice is shortening convalescence and lessening debility in these fields. Surgeons are getting patients out of bed much earlier after certain procedures, and new procedures are being advocated particularly because time of bed confinement is reduced by their use.

A Program for the Patient Destined for a Prolonged Hospital Stay—Of necessity, many medical and surgical patients must remain in bed for a considerable length of time. Very often the physician's interest, very acute during the period of diagnosis, surgery or early treatment of a

given case, lags with the eager anticipation of other newer, more interesting diagnostic or treatment problems. The interesting case of yesterday becomes the forgotten indifferently treated patient of today. Patients whose convalescence is prolonged have many hours for reflection. Unfortunately some cannot lift themselves by their boot straps. They lapse physically and mentally into a desultory static phase for no other reason than that nothing is being done for them. These patients not only need physical rehabilitation but often psychic stimulation as well.

The patients who are doomed to chronicity are the next problem to be considered. These cases represent what is probably one of the greatest needs in medicine today. How can this large group of patients best be cared for? The total recovery possible in a given case will depend on the plan for convalescence which his physician chooses. Detail during convalescence will have much to do with determining the extent of ultimate incapacity.

One of these details is the application of *therapeutic exercise* during the illness proper or during convalescence where specific indications exist for its use. Exercises are utilized in rehabilitation in the following classifications:

1 *Exercises to enhance tissue drainage and improve circulation* In convalescence and rehabilitation such applications are elevation and depression exercises of the extremities instituted before active ambulation is started. The dangling of legs several times daily prior to ambulation builds up circulatory tonicity prior to adding the load of walking attempts to the patient's routine. Massage and periods of elevation of the extremities are given in conjunction with such exercises if the tendency to edema after dependency is too marked.

2 *Exercises to improve range of joint function* through relaxation of muscle spasm, or stretching of tissues and freeing of adhesions. Such routines are useful in the care of arthritics who have been long immobilized, burn cases, orthopedic and traumatic cases, and hemiplegics. Hemiplegic patients are one of the most neglected types of patients seen in practice today. The physician treats the patient following the acute etiological incident, and when stabilization occurs he too often leaves him to find his own way through ambulation. These patients should be treated early with passive motion of all joints to avoid restriction of joint movement in the presence of spasticity. Splints likewise may be helpful. Gentle stroking massage and muscle reeducation should be given throughout the course of the illness. Too often, though the pathologic involvement is lessened centrally, these patients are not taught to pick up function at the periphery. Close observation of the cause of incoordination in each case should be made and efforts made to smooth out function through reestablishment of lost patterns of function by strict disciplinary muscle reeducation. There would be far less resultant disability in this group under such a routine.

Arthritics³ with prolonged swellings, especially rheumatoid arthritic patients in whom sedimentation rate remains elevated, must begin ambulation with extreme care. Often the smallest amount of exercise is injudicious. Splinting against deformity, heat therapy, and simple nonweight-bearing bed exercises may be all that can be carried out for a considerable time. Often attitudes of flexion deformity are not actually due to contracted muscles but rather to weaknesses in extensor groups. Discrimination is necessary here. Maintenance of muscle balance is important in the ambulation of these cases. Other types of exercises also apply to this group.

3 *Exercises to improve muscle power* These exercises are admissible in any convalescent patient, and in certain pathologic processes are the most important element in the patient's rehabilitation. Early considerations as to power requirement in muscles essential to ambulation must be made. Much loss of time during later hospital stay will be saved if proper exercises are instituted early. Patients who will use crutches need triceps muscles and scapula fixators and a hand grip. Patients who will walk with leg disabilities need to have the abdominals strengthened. Trapezes over beds are of great help in assisting patients to move themselves about, but they also overdevelop flexor muscles at the expense of extensors. The extensors always suffer in bedfast patients. It takes time to develop muscle power. Muscles can only develop through active volitional use of the muscles to be strengthened. The effort must be stepped up and fatigue avoided if consistent progress is to be made. This developmental type of exercise is indicated in such diseases as myelitis, especially the infectious myelitides including poliomyelitis, and in orthopedic and traumatic cases.

4 *Exercises to preserve function and preclude atrophy* have been dealt with elsewhere in this paper.

5 *Exercises to improve coordination* are extremely important in neurologic syndromes of central and cord origin. They are likewise important in teaching walking technics following disability. Walking exercises are those for coordination and also for building up muscle power. They must start with simple balancing with attention directed toward how weight is shifted in locomotion; then steps are taken, then with increased power the base of the step is narrowed and measured distances for walking are gradually added. When possible, coordination in walking is best started in weak patients with the greater part of the body immersed in water.

While discussing coordination exercise, it is important that occupational therapy be brought into the picture. As soon as a patient has two joints in function, in the rehabilitation of an injured member, coordination is possible. The coordinated efforts directed toward some definite incentives as are found in occupational therapy are considerably more acceptable to the average patient than are exercise routines.

per se Functional use of occupational therapy to improve facility in movement represents one of our most useful therapeutic agencies

6 *Exercises to step up metabolism* are indicated in those cases in which obesity becomes a complication For example, in orthopedic and arthritic cases, bearing of excessive weight interferes with mechanics of locomotion, or aggravates an inflammatory condition The institution of such exercises in asthenic patients may be the first step toward making them feel alive Such metabolic exercises must ultimately be quite vigorous if they are to be effective Hence, they can only be adapted to cases in which cardiac disability is not a factor Deep breathing exercises likewise improve circulation and increase vital capacity in such patients

7 *Exercises for postural improvement* are indicated in the convalescence of many patients Proper distribution of gravity in posture will hasten convalescence Weak, tired patients are apt to assume postures of relaxation Such attitudes may become habitual if no attention is paid to them Continuation of poor posture often results in development of structural pains due to poor body mechanics These exercises are a combination of muscle strengthening, coordination, balance and rhythm

The Need for a Convalescent Ward, and for Intramural Hospitalization
—There comes a time in the illness of patients when it is no longer appropriate or necessary for them to remain in the hospital They have become totally dependent on hospital service The burden of them appears such that it is frightening to their families It may be weeks or months before they will be mentally and physically able to return to anything approaching the routine of life to which they were previously accustomed Social service or friends cannot provide for their needs Their deficiency is within themselves Many have only sufficient strength or concentration to carry on alone for but a brief part of each day Many have residual disabilities, or routines for recovery which require skilled assistance or nursing care Many require special services, as physical and occupational therapy, which cannot conveniently be brought into their homes or which cannot be provided in a convalescent home Patients presenting such subacute or chronic needs for physical restoration may require months to prepare themselves to cope with the daily routine of living and to take their places in society Some never will be able to do so I particularly have in mind the rheumatic and arthritic group, those with progressive lesions of the central nervous system, the hemiplegics, and patients with advanced peripheral vascular disease, chronic osteomyelitis and surgical tuberculosis Necessary treatment is expensive, time-consuming and definitely out of reach of all except the so-called "well-to-do" class of patients (the small minority) A great and growing need exists for institutions equipped to care for such temporarily or permanently invalided patients—institutions supported by private or public funds.

Some measure of security has been provided for the tuberculous, the neuropsychiatric, the blind, the cardiac, the crippled child, and the aged and infirm patient.

In the care of the convalescent patient needing an extended hospital stay, much could be done to expedite his exodus from the hospital and something should be done to make less urgent his discharge from the hospital before he is able to carry on by himself. Two definite needs present, a need for a convalescent ward, and a need for intramural hospitalization.

Many patients admitted to general hospitals with immediate needs for medical and surgical care ultimately have need for extended hospitalization. It is not considered safe to transfer many such patients to convalescent facilities even though such arrangements might contribute much that is psychically and physically advantageous to convalescence. In these patients, the major needs of treatment have been met, convalescence is definitely established, but it is advisable that the patients be kept under observation by the doctor or the service who have followed them through their illnesses. A certain amount of treatment still is imperative and some types of ambulation must be carefully controlled while the patients are being rehabilitated. There is still a possibility of sudden retardation of restoration due to unpredictable but not unusual sequences or complications common to patients with their particular ailment, or which may follow the procedure to which they have been subjected. We cannot remove these patients from our direct supervision. Yet they occupy beds on active medical and surgical services, precluding the admission of more acute needy cases. On teaching services they slow up the admission of good teaching case material. Such patients are found in all divisions of a general hospital. A few examples are the postpneumonia and postcardiac patients, rheumatic and arthritic patients,³ patients with certain types of myelitis, certain fracture patients late in their treatment, orthopedic patients for whom rest and physical therapy rather than surgery are indicated, or who have been subjected to surgery but must be under observation, patients who have had cerebral accidents, and a host of others which must occur to us as we concentrate on this problem. All these patients probably need, among other things, some form of physical therapy or occupational therapy.⁴

There is a certain point in the care of these patients when we wish we could move them along. They are in wards with other patients much sicker than themselves. Rest is disturbed and surroundings are depressing. Psychologically they need more hopeful and stimulating surroundings. They need special care of a different type—rehabilitative—tonic—ambulatory. These needs are common to all. At this time their condition should be carefully weighed. Their treatment is probably stabilized and could be carried out with less particular attention previously necessary. On the other hand, the physical recov-

which they require could be much better handled were they grouped together in one place. If months of such care are indicated, we have one problem, if weeks only are necessary, it is quite another. Those requiring a reasonably short stay might be cared for in a rehabilitation ward. This ward might best be under the direction of the one in charge of Physical Medicine, as all such patients will require those facilities, and the personnel in Physical Medicine are best equipped technically to work with these patients. The nurse in charge of such a ward should not only be trained in nursing but also physical therapy and rehabilitation. Such a ward should be provided with adequate space for special exercise treatment, equipment for resistive exercises, underwater exercise facilities, ample supplies of crutches, canes, walkers, and other essential equipment.

These needs are being met at present in a most disadvantageous way in most institutions. Much time is lost in transporting patients and equipment, often long distances. There is a lack of uniform direction in plan of treatment because often the physician who is brilliant in giving the care in earlier stages of the illness is quite ignorant of the psychology and technical procedures required for rehabilitation. A rehabilitation ward working in close cooperation with the physicians most interested in these cases would make for economy of time and personnel. An improved psychology would exist in the patient who would feel that he is progressing in the right direction. He would be sharing similar problems with his co-patients in the ward. This would unquestionably accelerate his movement toward home and ultimately send him home less of a burden to himself and his family.

There is need for such a facility to care for *poliomyelitis* patients if they are to be admitted to a hospital in any number. There is a growing appreciation in contagious disease hospitals that such institutions are not geared to the treatment of poliomyelitis. The need for isolation is now considered less than is the need for early treatment. General hospitals are planning to accept these cases under routine precautions. There is no early treatment for poliomyelitis⁵ except symptomatic care to preserve life, relieve pain and conserve energy. Later, treatment is indicated to bring maximum comfort to the suffering patient, prevent possible deformity, increase flexibility, and then guide the patient through a period of muscle training, coordination and ambulation. The care the first two weeks will consist of neurologic and pediatric treatment, nursing and some physical therapy. After two weeks the case becomes primarily a problem of physical medicine and orthopedic consultation. These patients fit well into the class of patient who should not be in general wards, but in a rehabilitation ward under direct supervision of Physical Medicine.

What is to be done with those patients whose rehabilitation is to be long extended? Unfortunately, hospitals for chronic diseases are rela-

tively few and widely scattered. Many of these patients have a good prognosis for ultimately resuming a normal existence. Removal to another hospital would not be the best plan. Much better care and follow-up could be carried out by the staff which has carried them over the hump of their illness. Though the further counsel of numerous physicians may be required, it seems uneconomical to spend time re-orienting an entirely new staff to the patient's particular needs, with the hazard of conflicting medical opinions. Convalescent homes are not the answer even if directly associated with a hospital. Such abodes should be set up and operated as interim resting places where no treatment is required during the patient's convalescence.

The requirement is for an intramural convalescent rehabilitation hospital, preferably physically adjacent to the hospital where early care has been given. Admission to this hospital might be limited to patients whose prognosis for ambulation and self-care on admission is good. All these patients should be able to walk out of the door when discharged. Incurable patients should be barred from admission. The facilities should be sufficient to provide not only special rehabilitative procedures but also any postsurgical and medical needs as remain necessary during convalescence. Physical Medicine will hold an important position in this medical institution.

This specialized hospital being adjacent to the general hospital will have available any and all consultants to meet special problems. Records will be easily available for follow-up comparisons, and should new emergencies arise, transfer back to the original hospital would present no problem. Progressive rehabilitation, especially in orthopedic and plastic cases, could be continuously carried forward with the patient retaining maximum of function between a series of operative procedures. Ample and diverse facilities for recreation and physical exercise indoors and outdoors should be available to these patients as the physical bans are lifted with progress of convalescence. It might well be that the occupational activities of patients at this stage be guided into prevocational channels.

Rehabilitation and Reconditioning—In the armed forces we are seeing two different classifications set up. Rehabilitation and Reconditioning. In the final analysis, rehabilitation probably accents special medical procedures necessary to mental and physical restoration. Reconditioning has two places in a patient's illness. Early in his illness, reconditioning is used for the prevention of loss of vitality to which a patient, however ill, may be subject. Later in the soldier's illness, after physical inhibitions are reduced, he is placed in a reconditioning program to provide physical activities which build up his strength at an accelerated rate, progressing toward fitting him for return to full active duty. Reconditioning programs are under medical supervision and include recreation as well as direct group exercises. The armed forces have

taken advantage of the special knowledge of those trained in Physical Education to assist with reconditioning Occupational therapists are also included in the reconditioning set-up

This grouping in the program of reconditioning works out satisfactorily, and in wartime such is the outstanding requirement, however, it leaves much for improvement Physical therapy has been placed under Orthopedics in the Army organization There are certain doubts as to the soundness of such an arrangement One conversant with the broader concept of physical therapy and its close tie to occupational therapy in treatment must wonder whether it might not be awkward to facilitate the use of physical therapy in neurology, psychiatry, plastic and general surgery, under such a plan

The Place of Physical Medicine in the Hospital Organization—Physical medicine will some day probably assume a position of more major importance in the hospital organization plan It will be set up as a department self-sufficient to service all the treatment and rehabilitative needs which can only be made available through the specialized equipment, education and skilled technics acquired by personnel trained in physical medicine, i e., doctors, physical and occupational therapists, special orthopedic nurses, and recreationists Education in physical medicine is being stimulated by this war, and programs are developing in various medical centers⁶ directed toward basic research supporting procedures in physical medicine, and toward making available accumulated knowledge in the field of physical medicine

Physical therapy can be of great value in *prophylaxis* A routine of massage to the lower extremities in acute cardiacs, pneumonia patients, and postoperatively to hernia cases, can be very helpful in preventing the occurrence of circulatory complications Routines of exercises for bedfast patients who are not generally ill, but whose incapacity is limited to a localized condition in one or two extremities, will do much to maintain efficient circulation, lessen lowered resistance and prevent atrophy due to disuse Such patients will be in better condition when the time for ambulation arrives The organization of such a routine throughout an institution requires careful planning so as not to interfere with purely medical routines

Earlier Ambulation of Patients Is Indicated—A scheme for earlier ambulation of patients in hospitals should be worked out The Army Air Forces have done a fine piece of work and have proved definitely that virus pneumonia patients do best when at a certain time in their resolution they are rather rapidly and progressively ambulated At just what moment it is expedient to ambulate patients of all kinds will require careful consideration There can be no doubt that our physiology normally follows the general rule of "supply and demand," and we have learned the hard way that perhaps these demands should be created earlier Note, in this respect, osteoporosis due to disuse and the improvement in bone healing with weight-bearing, the response of func-

tional hearts to exercise, the rapid improvement in function and reduction in periarthritic disabilities with judicious activity, the need for constantly progressive effort in treating weak muscles, the moderated activity in treatment of peripheral vascular cases, and many other such examples

Problems of the Patient about to Be Discharged—There is another gap in treatment needing exploration. Certain patients are discharged from the hospital who, after partial rehabilitation has been carried out, can safely be returned to their own particular environment. Before they can be discharged, consideration must be given to the sort of environment to which they are returning. Is the patient male or female, married or single, child or adult, or aged? Is he or she returning to a home, with all that word implies, to a furnished room, or to some other domicile? Is he entirely capable of self-help, or in need of physical assistance? Will he need treatment? If so, how often? Will it be possible for him to return to the out-patient clinic or doctor's office? If so, will he need transportation, or is his home so far away that such visits would be too time-consuming or require too much effort to be practicable? Is the patient intelligent enough to be entrusted with home routines? These are just a few of the considerations of this moment.

The social service workers can be very helpful in ascertaining the answers to many of these questions. Many outside agencies exist, such as visiting nurse groups, crippled children's programs and associations, the Red Cross, and community workshops,^{7 8} which may render assistance in special cases.

There is often an hiatus in care at this point. Treatment considered necessary the day prior to discharge of the patient is conveniently forgotten because we do not know how to organize its inclusion after discharge. This hiatus would be far less were the rehabilitation ward and intramural hospital in common existence and well integrated with the host of rehabilitative agencies at present available but far too little publicized. The problem boils down to education, publicity, utilization and integration.

FEDERAL, STATE AND INDUSTRY'S INTEREST IN REHABILITATION

The federal and state governments have been interested in rehabilitation for years. Programs for crippled children exist in most states, orthopedic programs in many. Large insurance companies have been forced to organize for rehabilitation of their insured.⁹ Many would be anxious to cooperate with organized medicine in developing rehabilitation facilities. Insurance companies spend thousands of dollars annually in compensation fees, which expenses could be grossly curtailed if some of the existing laws governing compensation could be rationalized.^{10 11} Free choice of physician is a democratic procedure but often leads to irregular practices and scandals, to ambulance chasing

and often the patient and the insurance companies are both victimized as a result

Industrial medicine cannot be passed over in discussing rehabilitation. Such programs have to do with maintenance of a high standard of health, improved working conditions, and also care for employees when ill or injured. The overall treatment of the industrial medicine problem is one intimately entangled with other problems such as pre-paid medical care, workmen's compensation,¹³ rehabilitation,⁴ and employment of the handicapped.^{11, 13, 14, 15} Further consideration of industrial medicine cannot be included in this opus. Similarly, the problems of the returning veteran and the broad subject of vocational rehabilitation for the handicapped²² are not subjects to be discussed under the title of this discourse. A few recent references are included herewith for those interested.^{16, 17, 18, 23}

REHABILITATION IN THE HOME AND THE DOCTOR'S OFFICE

Up to this point I have largely concerned myself with hospital problems, that is, to patients admitted into the hospital. There is a large group of patients who require rehabilitation after leaving the hospital. Many other patients never are admitted to hospitals but are encountered in medical and surgical practice in the home or the doctor's office. Those treated in the home will be managed much as they would be handled in the hospital except that laboratory assistance and certain forms of treatment are more difficult to arrange. Most physicians develop means in their practice to meet these problems. Ambulation may suffer due to lack of available assistance. Each physician should make it his duty to acquaint himself with all special services available in his community upon which he may call to help him with home-bound patients. In his office practice he may have space and equipment for physical therapy. If so, he should have well trained assistants to give such treatment. Likewise, he should avoid the pitfall of using physical therapy promiscuously on his patients. Physical therapy should never be given to a patient unless a particular physiological response definitely beneficial to the patient can be anticipated. Consultation advice in rehabilitation should be sought when the physician feels insecure as to what his next step should be.

Rehabilitation of patients in rural areas is difficult due to time, distance, transportation problems and lack of concentration of facilities. Public health agencies, traveling clinics and orthopedic and state rehabilitation programs are all available to assist the physician and his patient. Federal funds¹⁰ in equal amount to state expenditures assist in providing means for physical restoration. The integration of such a program is well demonstrated in the Ohio Plan.²⁰ The Peoria Plan²¹ is an excellent example of what a local city in Illinois has worked out for care and placement of the handicapped. This plan as outlined is adaptable to smaller communities.

REHABILITATION OF SPECIAL CLASSES OF PATIENTS

The Mentally Ill—Rehabilitation in relationship to the mentally ill patient has not been mentioned. Such considerations are not admissible as such in this paper. Psychiatry has pretty well grooved channels in this field. New methods of group treatment for war psychoses are being explored and found practicable. Many physically ill patients lapse into the group of mentally ill. Fewer of these lapses would occur were a live rehabilitation program available in the hospital setup. Functional neurologic conditions respond to well directed physical and occupational therapy procedures when closely integrated with proper psychologic treatment.

Children with Cerebral Palsy—A special group requiring rehabilitation are children with cerebral palsy. Much can be accomplished with these patients. It is imperative that they be discovered and their condition evaluated as early as possible. The location and degree of the pathologic involvement should be determined, also whether or not it is static or progressive. The patient's intelligence quotient should be determined, and we must include in our evaluation the extent that the intelligence quotient is influenced by lack of skill or speech deficiency on the part of the patient. Certain of these patients will require surgical assistance and orthopedic appliances. Close cooperation between neurologist, the specialist in physical medicine, and the orthopedic consultant will be necessary in planning the rehabilitative program of these patients. The children are young, their futures will be measured in terms of self-help, locomotion, and probable educability. The possibilities should not be overestimated. The preschool child should be directed toward maximal utilitarian function. The preschool child should be treated with physical therapy particularly if he is inordinate, athetoid or choreic. Even if spastic, much can be done for him in these tender years and anticipated deformity can be lessened.

The problem of the child with cerebral palsy is a community problem. Here the slogan of the Army, "the greatest good for the greatest number," holds very well. The community owes each of these unfortunately affected children a chance for rehabilitation. Public and private funds are available and should be utilized to the fullest extent. Local departments of health and education should combine their efforts toward case finding and continuous treatment. Hospitals and schools should be brought together in treatment. Transportation problems should be studied and where possible a common denominator for transportation covering treatment and education should be estimated. Treatment should be entirely under medical supervision, and only by skilled technicians. Home teachers should be provided where necessary. The children's parents should be progressively educated to the problems surrounding these children and their cooperation maintained throughout the treatment period. Vocational ~~and~~ ^{is} brought into the picture at the proper moment. The entire

should be set up with the least amount of accent on each individual's personal handicap, consistent with individualization of his case. The hopeful end results are independent locomotion, complete self-care, a minimum of "cripple complex," and the hope of individual maintenance through vocational training.²²

CONCLUSIONS

The impressions set down in this short treatise may help to crystallize thinking on rehabilitation. The aims of rehabilitation and convalescence are to aid the patient toward regaining his physical strength and normal facility of movement, to rejuvenate the spirits of an individual and minimize any tendency to lasting disability following illness or injury.

It may be concluded that

1 Total rehabilitation requires the combined efforts of many individuals and agencies—medical, social, financial and others.

2 The use of agencies of physical medicine are imperative to any rehabilitation program.

3 There is need for definite factual consideration of many problems which present themselves during rehabilitation and convalescence.

4 Changes in plant and administration will be necessary if rehabilitation is to be carried out effectively and efficiently in the modern hospital.

5 There is need for the development of a new type of convalescent hospital.

6 There is need for informative publicity both to the public and the medical profession as to services available to assist in rehabilitation.

SYMPOSIUM ON MEDICAL EMERGENCIES

NONSURGICAL EMERGENCIES ENCOUNTERED IN THE PRACTICE OF DERMATOLOGY

PAUL A. O'LEARY

ALTHOUGH there are but few diseases of the skin which may be classified as actual emergency conditions, nevertheless, there are several forms of dermatitis of the acute inflammatory type in which the therapeutic measures should be employed as promptly as possible after the diagnosis has been made. When these agents are specific in their effect, their immediate use becomes essentially an emergency procedure.

ACUTE DERMATITIS

Although an acute inflammation of the skin characterized by erythema, edema, vesiculation and sometimes bullous formation may be due to a variety of etiologic agents, it is advisable to apply the therapeutic efforts immediately and postpone the effort to determine the cause of the dermatitis until the acute reaction has subsided. The reason for so doing is that the search for the cause of an acute dermatitis usually requires the use of the "patch test" and if the irritating substance which caused the dermatitis is applied to the skin the dermatitis may be severely aggravated and extended. It is well to bear in mind that a skin which is the site of an acute vesicular reaction as the result of contact with some irritating substance has become highly sensitive, and during the acute phase of irritation it will react unfavorably to substances it tolerated readily in a normal state. This not only applies to the area involved but is to be noted also on almost any part of the patient's skin. This fact is of significance in the consideration of the local therapeutic applications to be employed. While on the subject of hypersensitivity the mechanism of which is not thoroughly understood, comment will be made on the significance hypersensitivity plays in the result of the local measures used in the treatment of acute

dermatitis This is frequently noted in a case in which a patient consults a physician shortly after the onset of the dermatitis and the wet dressings applied give no comfort The use as wet dressings of three or four different medicaments in weak solutions for several days likewise fails to relieve the annoying itching, and all the while the dermatitis is extending and becoming more severe This failure to respond to treatment is frequently the result of the increasing hypersensitivity and it is during this period that the local use of strong applications will aggravate and extend the condition and, likewise, the use of preparations well tolerated by most patients may afford no relief When one switches back and forth between the mild wet dressings used in weak dilutions four or five days or longer may be required for the dermatitis to reach its peak and it is the last application employed that is usually given the credit for controlling the dermatitis while, in reality, the improvement is the result of the hypersensitization process having reached its peak Most of the local applications which previously failed will now be found to be comforting to the patient The recognition of this phenomenon is of utmost importance in the care of a patient with an acute vesicular dermatitis, of contact origin, especially as it applies to the selection of the drugs and the manner in which they are applied to the skin

A skin which is the site of an acute inflammatory reaction with vesiculation, pustules, oozing and crusting is seldom helped by a greasy or oily application because the serum produces a film which prevents the drug from coming in contact with the skin It is in such situations that the use of a wet dressing of a weak astringent or mild antiseptic solution is indicated Among such applications the following have gained popularity because of their demonstrated value solution of aluminum subacetate 0.5 per cent, potassium permanganate solution 1:15,000, boric acid solution 5 per cent, silver nitrate solution 0.1 per cent, and physiologic salt solution 0.9 per cent

There are several factors in the application of a wet dressing that are essential to its successful use First and foremost, the dressing must be kept wet continuously This is accomplished by using a large amount of gauze held on by a bandage which is not too tightly applied and is not covered by an impervious dressing unless heat is to be applied The upper and lower ends of the gauze should be loose enough so that the solutions can be easily and frequently applied at the openings rather than poured on the middle of the bandaged area where most of it is not absorbed by the gauze but runs off the bandage onto the floor or bed It is advisable to remove the entire dressing every three or four hours and aerate the gauze by fluffing or agitating it and, if there is much pus present, a complete change of the gauze should be made three or four times in twenty-four hours The skin may become macerated if the dressing is kept on too long or is too wet, therefore, the dressings should be removed for fifteen to thirty minutes every twelve hours to allow the skin to "dry out" The failure

of a wet dressing to produce relief when properly applied may be due to one of the following factors the solution may be too strong, its pH may be too high or too low, or the dermatitis still may be in the process of spreading. When such situations arise, the type of the application should be changed or weaker dilutions used and a mild sedative employed. As the vesiculation and edema subside and the process becomes less acute, the wet dressings may be discontinued and a mild grease applied. The following ointments may be used in this phase of the disease: 3 per cent ichthyol in zinc oxide, 3 per cent ichthyol in aquaphor, equal parts of aquaphor and lime water, or calamine lotion followed, when it has dried, by boric acid ointment.

Frequently, if the dermatitis has completely reached the subacute phase, the switch to the ointment can be made without discomfort, on the other hand, if the dermatitis is still acute, the ointment may cause discomfort, in which case it is advisable to return to the use of the wet dressing for two or three periods of two or three hours each. It is only in the late or chronic phase that stimulating applications should be employed, and then it is advisable to use them in weak strengths. Either 1 per cent of salicylic acid, 1 per cent of benzoic acid, 1 per cent of *pix liquida*, or 1 per cent of *liquor carbonis detergens* may be incorporated in a suitable base during this phase of the disease.

When the dermatitis has subsided, search may be made for the offending agent by the patch test, that is by applying small amounts of the suspected substance to the skin. This procedure must be used with some caution because, if a large amount of the substance in a strong dilution is applied to the skin it may cause a considerable aggravation of the dermatitis. The patch test is not always specific even though the substances which caused the dermatitis are applied. Certain substances, even in weak strengths, also may produce a 'burn' rather than a specific vesicular reaction. Experience with the procedure and with a large number of substances is necessary to evaluate the test properly. It is unfortunate that the cause of acute vesicular dermatitis cannot be determined in every case.

USE OF PENICILLIN

The following acute inflammatory diseases of the skin are materially helped by the use of penicillin, in fact, in several of them the result may be said to be specific because the effect is so rapid and complete.

Anthrax—This is a disease usually found in persons who handle hides, hair wool or the carcasses of animals. A small epidemic which occurred in this country in 1919 was due to infected shaving brushes that had been imported.

The initial lesion, usually single, appears as a single papule which soon develops a bullous center. The reaction rapidly becomes very intense, the bullae rupture and a dark sphacelus results, while groups of vesicles or pustules develop around the periphery of the original lesion, which has now become markedly indurated.

The constitutional symptoms may be severe and consist of fever, delirium and prostration. Death may occur from septicemia or the constitutional symptoms may be mild and insignificant.

The diagnosis is readily made by recognition of the bacillus anthracis in smears taken from the pustule. Treatment consists in the immediate administration of penicillin in doses of 25,000 Oxford units every three hours. Murphy, La Boccetta and Lockwood recommended that a total of 400,000 Oxford units be given in four days. Wet dressings of penicillin may be employed in strength of 400 units per 100 c c of saline solution, and penicillin may also be injected into the tissue surrounding the original lesion. Surgical incision, excision or manipulation of the primary lesion is definitely contraindicated.

Cellulitis, Furunculosis and Carbuncles—These lesions are also helped according to Herrell in varying degrees by the use of penicillin given intravenously or intramuscularly and applied as a wet dressing. The earlier in the course of the infection that the administration of the penicillin is started, the better the results. Likewise, with the use of penicillin, surgical incision of these infections is seldom necessary and injection of penicillin into the inflamed area is not advisable.

Erysipelas and Erysipeloid—The low-grade migrating forms of erysipeloid that gradually extend until, in some cases, they will involve the entire skin surface over a period of several months, respond rapidly to penicillin given by the intramuscular or intravenous route. The dose found to be effective has been 100,000 units given intramuscularly every three hours until the involution occurs.

The same results have been observed in the majority of patients with the acute type of erysipelas treated with penicillin in the manner described.

Impetigo Contagiosa—Roxburgh, Christie and Roxburgh have reported the successful use of penicillin as an ointment for the treatment of impetigo contagiosa and infantile impetigo, which frequently are difficult to eliminate from a nursery. They recommended the use of an ointment containing 400 Oxford units of penicillin per gram of lanette wax and petrolatum.

Infection Due to Burns—Likewise, the reports in the literature indicate that the secondary infection of burns of the skin may be controlled or prevented by the use of penicillin both as a wet dressing or given systemically by either the intravenous or intramuscular route.

NONSURGICAL EMERGENCIES IN CASES OF THORACIC DISEASE

HERMAN J MOERSCH

THE thorax is heir to many diseases, most of which, under certain circumstances, may necessitate immediate medical attention. It is not always possible to state with certainty what comprises a true medical emergency as distinguished from a surgical emergency, or at what point one blends into the other. With this realization in mind, an attempt will be made to consider primarily the emergency conditions which generally are treated medically.

HEMOPTYSIS

To the patient who suddenly expectorates blood for the first time, the experience is indeed alarming and looked upon as very much of an emergency. Hemoptysis also should be viewed by the attending physician as an emergency, at least until its cause has been adequately determined. Of the more common causes of hemoptysis, I shall consider tuberculosis, acute edema of the lung, pulmonary embolism, pneumonia, bronchiectasis, pulmonary abscess, broncholithiasis, carcinoma of the lung, adenoma of a bronchus, and idiopathic bleeding.

Tuberculosis—Tuberculosis is the most frequent cause of hemoptysis, and bleeding may be the first warning of this disease. It is estimated that in approximately a third of all cases of pulmonary tuberculosis hemorrhage occurs before the diagnosis is made. The initial hemorrhage is seldom fatal. It has been estimated that hemorrhage probably occurs in two-thirds of all cases of pulmonary tuberculosis at some time during the course of the disease. Men are somewhat more prone to bleed than women. One is not justified in making a diagnosis of pulmonary tuberculosis on the basis of hemorrhage alone. There must be other supporting evidence of the disease such as definite roentgenologic signs or the demonstration of *Microbacterium tuberculosis* in the sputum. The importance of early and prompt diagnosis of pulmonary tuberculosis is self-evident, and hemoptysis due to this disease truly constitutes an emergency until proper and adequate treatment is started. The treatment of pulmonary tuberculosis has been so well established that further consideration of the disease is not warranted at this time.

Acute Edema of the Lung—Acute edema of the lung comprises one of the most dramatic as well as terrifying of the pulmonary emergencies that must be treated medically. Expectoration of bloody sputum is often one of the most prominent symptoms. The patient may or may not expectorate copious amounts of sputum. The sputum is generally thin and watery, often frothy in consistency and pinkish in color. The patient's breathing is generally labored, noisy and bubbling.

in character, and is aptly designated by the term "death rattle." The patient's face and extremities are generally dusky in color and the superficial veins of the face, neck and upper extremities may be distended. As the condition progresses, the extremities become cold and blotchy purple in color. Percussion of the thorax usually reveals increased dullness over the posterior portions of both lower lobes. On auscultation, coarse, bubbling râles are found scattered over the entire thorax and are most audible over the trachea. As fluid accumulates in the pleural cavity, the breath sounds disappear at the base of the lungs.

The patient's condition is usually so critical that it is often impossible to obtain a satisfactory roentgenogram of the thorax. If it is obtainable, it may present a varied picture, usually resembling an extensive patchy infiltration with greatest density at the bases and in the hilar regions. It often reveals large, more or less circumscribed areas of increased density, which may occupy a considerable portion of the pulmonary fields. There also may be evidence of pleural effusion.

Any suppurative pulmonary disease in which there is an abundance of sputum may produce a clinical picture which simulates that of acute edema of the lung. Care must be exercised to distinguish the two conditions as the treatment to be employed varies greatly. The past history and the character of the sputum are of considerable importance in the differential diagnosis. If the sputum is purulent in character, the lesion is more likely to be inflammatory in nature. It must be remembered, however, that pulmonary edema may develop secondary to suppurative pulmonary disease, and when this occurs it may be impossible to state where one condition leaves off and the other begins.

Acute edema of the lung may be due to many factors. Anything that causes a failure of the left ventricle will bring about such a state. A common cause is the intravenous administration of excessive quantities of fluid, especially in the presence of acute renal failure and in cases in which the serum protein has been depleted. It may occur as a result of any condition that gives rise to an increased pulmonary capillary permeability, such as an acute infectious process. It also may result from chemical irritation or severe anoxemia.

Early and prompt treatment is imperative if the patient with acute pulmonary edema is to survive. Oxygen therapy is the most important treatment available for incipient or actual pulmonary edema. It should be used promptly and not withheld until cyanosis occurs. Oxygen is best administered by means of a mask, when it is administered in this manner, its concentration can be more adequately controlled and it may be given in higher concentrations than is possible when an oxygen tent is used. It may at times be of value to combine the oxygen with helium. Barach, Martin and Eckman have pointed out that, theoretically, it should be of value to administer oxygen with positive pres-

sure. Although this may be of some value in certain selected cases, thus far no completely satisfactory apparatus is available for the administration of oxygen in this manner. Venesection often may be of value in cases of acute edema of the lung. Diuretics such as anurophalline, given intravenously may be of help.

Pulmonary Embolism—Pulmonary embolism is one of the most serious of medical as well as surgical emergencies. Although hemoptysis occurs in pulmonary embolism it is usually one of the later manifestations. There are certain conditions which seem to predispose to embolism. Among these may be mentioned operations especially those for malignant lesions. It is most common among patients who are obese, among those suffering of heart disease, and among those who are more than forty years of age.

There is very little to do for a massive pulmonary embolism. As a matter of fact, the patient generally has died before aid can be summoned. A great deal, however, can be done in the prevention of pulmonary embolism and in the care of the patient who has had a nonfatal pulmonary embolism. Prompt recognition of a nonfatal embolism is imperative, for the victim is in grave jeopardy, for a time of a recurrent and even fatal attack. A careful clinical history is of the greatest importance in the diagnosis of pulmonary embolism. Large pulmonary emboli usually are accompanied by sudden severe pain throughout the thorax. The pain is associated with dyspnea, severe weakness and a sense of impending death. The patient usually is drenched in cold perspiration and has a rapid and often imperceptible pulse, a lowered blood pressure and an ashen color and often appears in shock. Smaller emboli may give rise to a very similar picture, but more often this classic picture is lacking. Pleurisy, especially if associated with dyspnea occurring in the postoperative period, should cause one to suspect the possibility of embolism. Hemoptysis occasionally may be the first manifestation of embolism. Often the only inkling of a small embolus may be a sense of apprehension and anxiety associated with palpitation and dyspnea. Unexplained fever in the postoperative period may be the only warning of such an accident. Vines found in his study of postmortem material, that in 15 per cent of cases of pulmonary infarctions there had not been any clinical symptoms.

The physical findings in cases of pulmonary embolism are dependent on the site and size of the embolus. If the embolus has occurred close to the surface of the lung, there may be dullness to percussion and a pleural rub may be heard over the consolidated portion of the lung. The roentgenographic findings are only occasionally indicative of embolism and are extremely variable and best described as a unilateral chronic passive congestion with accentuation of the hilar shadow when compared with the findings on the other side. Electrocardiography often may yield highly significant findings which are suggestive of embolism, as has been pointed out by White and Barnes.

Much can be accomplished in the prevention of pulmonary embolism by constantly keeping in mind the prevention of stagnation of circulation. When pulmonary embolism has occurred and the patient has survived the initial shock, a great deal can be done in the care and prevention of further emboli. Barker has recommended the immediate intravenous administration of $\frac{1}{2}$ grain (0.032 gm) of papaverine and $\frac{1}{100}$ grain (0.00065 gm) of atropine to combat the tendency of reflex constriction of the pulmonary vessels. Barker, Allen and Waugh have demonstrated that dicumarol is of great value in preventing pulmonary embolism and Barker has considered its administration elsewhere in this number. Dicumarol requires twenty-four to thirty-six hours to exert its beneficial effect, should an immediate anticoagulating effect be required, heparin can be administered intravenously until the dicumarol has had an opportunity to take effect. It is important that the coagulating time of the blood be closely watched and kept at between fifteen and twenty minutes while heparin is being administered.

Pneumonia—Since the advent of chemotherapy in the treatment of pneumonia, this disease has come to be looked upon as much less of an emergency than it has in the past. It must, however, be classed as one of the most important of the medical pulmonary emergencies. Expectoration of blood is often one of the cardinal symptoms of pneumonia and may be the first sign to attract the attention of the patient and the physician to the fact that a serious pulmonary disease exists. Early and prompt diagnosis still remains an important factor in the successful treatment of this disease. The possibility of pneumonia must always be considered in any case in which fever, general malaise and coughing are present. It must be remembered that pneumonic processes situated centrally within the lung may present few physical findings and often cannot be demonstrated except on roentgenologic examination. Although bacteriologic studies are of value in the study of pneumonia, since the advent of chemotherapy they are not as essential as they formerly were.

Chemotherapy is the procedure of choice in the treatment of pneumococcic pneumonia, and in other types of pneumonia it should be given an adequate trial. Among the most generally used chemotherapeutic and antibacterial agents are sulfadiazine, sulfathiazole, sulfamerazine and penicillin. Pneumonia of the virus type does not, as a rule, respond to chemotherapy. When any reasonable doubt exists as to the type of pneumonia, chemotherapy is indicated. The method of administration, dose and precautions involved have been so thoroughly and completely considered in the literature that they will not be repeated here. It should, however, be pointed out that adequate nursing care and the use of oxygen, where indicated, are still valuable adjuncts in the successful treatment of pneumonia.

Bronchiectasis—One of the most common causes for recurrent hem-

optysis is bronchiectasis. The initial hemorrhage may be very alarming to the patient until the true underlying cause is established. As a rule, the amount of blood expectorated in cases of bronchiectasis is small and bleeding is likely to occur after overexertion. Occasionally, the volume of blood expectorated may be very large and immediate medical attention may be required. At times, the purulent secretions associated with bronchiectasis fail to drain properly and this gives rise to a clinical picture that closely simulates that of pulmonary abscess or pneumonitis. As a rule, attacks of chills and fever associated with retained secretion are self-limited, but other medical measures such as the use of chemotherapeutic agents or bronchoscopic aspirations of the dammed-back secretions occasionally may be required for relief. The possibility of a metastatic abscess of the brain secondary to bronchiectasis must always be kept in mind.

The diagnosis of bronchiectasis usually can be made readily from the history of a chronic cough, the typical character of the sputum, which generally can be produced by inversion of the patient, and from the presence of clubbed fingers and positive roentgenographic evidence of the disease. On physical examination, coarse rales generally can be heard over the site of involvement. At times difficulty may be experienced in distinguishing bronchiectasis from such lesions as tuberculosis, pulmonary abscess, benign and malignant lesions of the bronchi, foreign bodies, pulmonary stones and other pulmonary lesions. This is in part due to the fact that bronchiectasis frequently accompanies such lesions. Whenever there is any question as to the diagnosis or whenever surgical treatment is contemplated, bronchoscopic studies and bronchograms should always be employed, as this is the only method to determine the exact extent and type of involvement.

Early and prompt diagnosis is important in the successful treatment of bronchiectasis. When the disease is limited to one lobe, especially if the patient is young, the lobe can be removed surgically with very little risk and with excellent results. The more extensive the involvement and the older the patient, the greater is the surgical risk and the poorer are the postoperative results. If the disease is very extensive and unsuitable for surgical treatment, postural drainage, avoidance of colds and overexertion, and removal of foci of infection are advisable, and administration of penicillin, by means of a nebulizer or other chemotherapeutic agent, is worthy of consideration.

Pulmonary Abscess.—Pulmonary abscess should always be looked on as a medical emergency as prompt treatment is important. In cases in which a pulmonary abscess is neglected, the mortality rate is extremely high. It is well to recall that the onset of abscess of the lung may be as insidious as that of tuberculosis. Hemorrhage may be a prominent and dramatic symptom. Although the diagnosis of pulmonary abscess usually can be made from the history, physical findings and roentgenographic findings, it often is extremely difficult to distinguish this disease

from other types of suppurative disease of the lung. The etiologic factors involved in the development of pulmonary abscess are numerous indeed. In my experience, abscesses of the lung have been about equally divided between those that follow surgical procedures and those that do not. Tonsillectomy performed with general anesthesia and pneumonia have been the most frequent etiologic factors. Bronchoscopy and bronchography are often of great value in the differential diagnosis. Many pulmonary abscesses will clear up spontaneously under adequate rest in bed, but, as a rule, bronchoscopic aspiration or surgical drainage will be found necessary. The most important factor in the successful treatment of abscess of the lung is its early and prompt recognition.

Broncholithiasis—The erosion of a calcareous lymph node into the tracheobronchial tree may give rise to alarming pulmonary symptoms, including hemoptysis. The symptoms of broncholithiasis are dependent on the size and shape of the calculus and the degree and duration of bronchial obstruction. The extension of the calculus into the tracheobronchial tree is generally manifested by a sudden, severe, paroxysmal cough, usually associated with thoracic oppression, substernal constriction or a severe tearing sensation. The cough may be accompanied by a so-called asthmatoïd wheeze, to which the term "stone asthma" has been applied. At times, the symptoms are not as dramatic and consist of attacks of chills, fever, recurrent pneumonitis, malaise and loss of weight. Unless the patient has expectorated a piece of calcareous material, the clinical history and physical examination are of little value in arriving at a correct diagnosis. Roentgenographic demonstration of calcified material in the tracheobronchial tree is of considerable aid in suggesting a correct diagnosis. Bronchoscopic visualization of the calculus or calculi, or the expectoration of such material is essential for a positive diagnosis. Broncholiths should be removed as soon as possible, for if they are allowed to remain they may lead to serious sequelae. This was well illustrated in a case of broncholithiasis that recently came under my observation. Bronchiectasis and a metastatic abscess of the brain developed and the patient died. Broncholiths are best removed bronchoscopically.

Carcinoma of the Lung—Carcinoma of the lung properly should be classified as a surgical rather than a medical emergency. Inasmuch as early diagnosis is paramount for successful treatment and since the symptoms of carcinoma of the lung closely simulate those of other inflammatory diseases of the lung it is essentially the physician who must discover its presence. Hemoptysis is a common and often an initial symptom of the disease. In my experience, approximately half of the patients with carcinoma of the lung will expectorate blood and the amount of blood expectorated varies considerably. It is not uncommon for the clinical history of carcinoma of the lung to simulate that of pneumonia, and the expectoration of blood may be regarded as part

of the pneumonic process. In half of the cases of carcinoma of the lung that have been observed at the Clinic, a diagnosis of pneumonia had been made at some time during the course of the disease. The possibility of carcinoma of the lung must always be considered in any case in which a patch of so-called pneumonia does not clear up within three weeks. The cardinal symptoms of carcinoma of the lung are cough, hemoptysis, expectoration and recurrent attacks of fever. The most significant physical findings are lagging of the involved side of the thorax and suppression of breath sounds. The roentgenographic findings are of considerable value. Bronchoscopy probably offers the most valuable aid in arriving at an early and accurate diagnosis.

Adenoma of a Bronchus—Recurrent attacks of hemoptysis, usually of some intensity, occurring in a case in which the patient is less than forty years of age, either with or without associated physical or roentgenographic findings, should cause one to suspect the possibility of adenoma of a bronchus. Adenoma of a bronchus, if uncomplicated, usually can be treated successfully either bronchoscopically or by operation without a high degree of risk.

Idiopathic Bleeding—A group of patients consults a physician because of pulmonary hemorrhage, sometimes of severe degree, for which no adequate explanation is apparent. The clinical history and the results of physical examination and of roentgenologic and laboratory examination are to all purposes negative. There is no evidence to suggest a blood dyscrasia or vitamin deficiency. On bronchoscopic examination no organic lesion can be found but it will be detected that the least manipulation of the bronchial mucosa is followed by the oozing of blood. As a rule, curettage of the bronchial mucosa followed by the insufflation of sulfanilamide or one of its derivatives usually will cause a subsidence of bleeding. The factors involved in the production and relief of this condition are not clearly understood.

DYSPNEA

A large number of patients have sudden and often severe attacks of dyspnea of pulmonary origin and this condition must be looked upon as a true medical emergency. Among the more common pulmonary disturbances that cause such dyspnea I shall consider asthma, pneumothorax, massive atelectasis, cystic disease of the lung and pleurisy.

Asthma—The most frequent pulmonary cause of acute dyspnea is asthma. An acute severe attack of asthma, "status asthmaticus," truly represents a medical emergency. At the time of the acute attack it may not be possible or wise to attempt a complete investigation of allergens, but attention must be directed to the immediate relief of the patient. If there is obvious evidence of the presence of an allergic factor it should be eliminated promptly. Various agents are available in dealing with acute asthma.

Epinephrine administered hypodermically remains one of the most

useful aids in relieving acute asthma. A dose of 7 minims (0.46 c.c.) of solution of epinephrine hydrochloride is usually administered. This dose may be repeated as often as required. Epinephrine also may be administered as a spray or in oil, but when the drug is administered in this manner the dose is more difficult to gauge than it is when a solution of epinephrine is administered hypodermically. Aminophylline and ephedrine also have proved of great value in relaxing bronchial spasm. In cases of acute and severe asthma, the administration of oxygen or of oxygen in combination with helium may afford a great deal of relief.

Pneumothorax—Spontaneous pneumothorax is a cause of sudden acute dyspnea. The degree of dyspnea is dependent in part upon the degree of collapse of the lung. Patients may have complete collapse of one lung with no appreciable dyspnea, while at times a partial collapse will cause considerable distress. Bilateral complete collapse of the lungs produces severe dyspnea and will terminate fatally if not promptly relieved. Pain over the affected lung is usually an early symptom and varies considerably in character and degree. The pain may be referred to the abdomen or shoulder and may simulate the distress produced by an acute abdominal disease. Cough may or may not be present, if present, it is usually nonproductive. There may be a slight elevation of the temperature and a slight increase in the pulse rate. Classically, the physical findings should consist of absence of tactile fremitus and diminution or absence of voice and breath sounds over the involved side. Lagging respiration on the affected side frequently can be detected. A positive coin test is of value. All too frequently, even when a patient may be known to have a pneumothorax, it may be impossible to establish the side of involvement on the basis of the physical findings alone. Roentgenologic examination of the thorax is the most valuable method of diagnosis.

In most cases of pneumothorax, the condition will clear up without treatment other than rest in bed. If the pneumothorax is due to tuberculosis, treatment should be directed to this end. Moorman recommended converting the spontaneous pneumothorax into an artificial pneumothorax for relief of pain, and if the condition should accidentally be due to tuberculosis this would constitute good treatment. He also expressed the opinion that this procedure tends to aid in the formation of adhesions so that the pneumothorax will be less likely to recur.

If pneumothorax is associated with severe dyspnea, the use of oxygen may be of value. As a rule, it is necessary to use the oxygen for only a few days, for the patient tends to adjust himself rapidly to the pneumothorax. In case of bilateral pneumothorax or tension pneumothorax, immediate aspiration of air from the pleural cavities in addition to oxygen therapy may be necessary.

Massive Atelectasis—One of the most dramatic lesions of the lung

that may be classified as a medical emergency is massive atelectasis. This occurs as the result of obstruction of a bronchus, usually by a mucous plug. It is especially prone to occur after operations have been performed on the thorax and abdomen or after trauma. It is more likely to occur in cases in which patients have a low-grade infection of the upper part of the respiratory tract or have a tenacious type of nasopharyngeal secretion.

Massive atelectasis of the lungs manifests itself by dyspnea and cyanosis. Respiration rapidly becomes labored and is associated with a hacking cough, and the patient experiences difficulty in raising secretions. There is an elevation of temperature with an increase in the pulse rate. The patient may complain of a sense of tightness in the involved side of the thorax.

The physical findings in cases of massive atelectasis are usually very striking. There is a sudden respiratory lag on the involved side of the thorax. The apex beat will be shifted toward the side of involvement. Percussion will reveal dullness over the atelectatic area and the breath sounds will be decreased in intensity. Roentgenograms of the thorax are of great value in making the diagnosis. An opacity of the lung will be noted over the involved side, with elevation of the diaphragm, while the mediastinum will be found shifted toward the involved side.

The treatment of massive atelectasis is relatively simple and efficacious. Frequently the patient can be encouraged to cough effectively. If the patient who has undergone an operation can do this by holding the site of the operation firmly, he may expectorate the obstructing bronchial plug. The same thing can at times be accomplished by change of position. Hyperventilation of the lung with carbon dioxide and oxygen and deep breathing exercises will frequently suffice. If prompt relief is not obtained by these methods, bronchial catheterization or better, bronchoscopic aspiration of the secretions obstructing the bronchus will be followed by immediate improvement in the patient's condition and by prompt changes in the physical and roentgen findings. The earlier atelectasis is recognized and proper treatment instituted, the less danger there is of the development of secondary pulmonary complications. Chemotherapeutic agents should always be employed promptly when indicated.

Cystic Disease of the Lung—Recurrent attacks of severe dyspnea with cyanosis, nonproductive cough and asthmatic attacks, particularly in cases in which the patients are infants or children, should cause one to suspect the presence of cystic degeneration of the lung. In the case of older patients, progressive dyspnea with or without preceding respiratory infection warrants the same suspicion. The attacks of acute dyspnea are caused by a sudden trapping of air in the cyst owing to a check valve mechanism between the cyst and the bronchus. If there is free communication between the cyst and the bronchus or no communication at all, such attacks do not occur. The symptoms as might

be anticipated, may be fluctuating and progressive and may closely simulate those of spontaneous pneumothorax. The diagnosis is dependent primarily on the roentgenologic findings. In cases of cystic disease, as a rule, in contrast to pneumothorax, the pulmonary tissue contiguous to the cyst usually will be compressed downward and toward the base of the lung. In cases of pneumothorax, it is more likely to be compressed toward the root of the lung. Bronchography may be of value in the differential diagnosis. Artificial pneumothorax may at times be required to distinguish a cystic lesion from pneumothorax or emphysema. If the cyst should contain fluid, difficulty may be experienced in distinguishing it from tumor, abscess and localized empyema. If the pulmonary symptoms become acute as a result of the trapping of air, it may be necessary to aspirate the air as a lifesaving procedure. Lobectomy is the procedure of choice in cases in which the symptoms warrant it.

Pleurisy and Pleural Effusion—The patient suffering from an attack of pleurisy may experience pain of such severity that immediate attention becomes imperative. Care must be exercised to distinguish the pain of pleurisy from pain in the thoracic wall and pain due to diseases of the central nervous system or spinal column. Diaphragmatic pleurisy especially may offer difficulty in differential diagnosis.

A characteristic sign of dry pleurisy is the pleuritic friction sound, which is heard either as a fine rub or coarse leather creaking. The friction rub also is usually palpable. Usually, the friction and pain are increased by deep respiration. Roentgenologic examination is of very little value in diagnosis of pleurisy, although it is of considerable value in the determination of its cause.

The treatment of pleurisy varies with its severity. Frequently, local pressure over the thorax is all that may be required. The local application of heat in any form is often of benefit. The use of codeine may be necessary to control coughing, which may aggravate the pain. In severe pleurisy that is not controlled by the methods outlined, the blocking, with procaine hydrochloride, of the nerves of the skin overlying the site of pain will generally afford immediate relief.

Pleural effusion, which may or may not be an accompaniment of dry pleurisy, may often become so severe that dyspnea becomes very pronounced and immediate aspiration of fluid is necessary for relief. Careful study of the aspirated fluid is of considerable value in the determination of the cause. It is of interest that, if pleural effusion that is due to cardiac disease or that follows surgical procedures is excluded, if the pleural effusion is found to be bloody in character there is better than a 90 per cent chance that the effusion is due to carcinoma. If the effusion is purulent in character, it may be successfully treated by instillations of penicillin and by surgical drainage in cases in which treatment with penicillin does not prove successful.

OTHER CONDITIONS

There are numerous other conditions, such as aspirated foreign bodies, mediastinal tumors, mitral stenosis, aortic aneurysm and diaphragmatic hernia, which may constitute a medical emergency but they are generally classified as surgical or vascular in type. These will not be discussed at this time.

It becomes readily apparent that the thorax, as the abdomen, is the site of many acute diseases and that early treatment is of paramount importance.

NONSURGICAL EMERGENCIES IN OBSTETRICS

JOHN E. FABER

THE obstetrician perhaps more than any other medical specialist requires special training and equipment to cope with the emergencies that occur constantly in his practice. Most of these emergencies can be managed on a medical basis.

In the field of obstetrics most deaths can be classified as attributable to three causes, as follows: (1) toxemia, (2) hemorrhage and (3) infection. Prenatal care and the use of chemotherapy and penicillin in the last decade have effected a marked reduction in mortality in the first and third groups but the mortality in the second group remains high. It is earnestly hoped that within the next few years increasing knowledge concerning transfusion of whole blood and plasma and their substitutes also may effect a major reduction of mortality due to hemorrhage.

There are, of course, emergencies due to conditions other than toxemia, hemorrhage and infection but since they account for a negligible portion of deaths in the field of obstetrics and since space is limited, they will not be discussed here. Consequently, I will outline the differential diagnosis and the routine management of only medical emergencies attributable to the three previously mentioned causes.

TOXEMIA

Toxemia may occur either early or late in pregnancy. Pernicious vomiting and chronic hypertension are evident early. Late toxemia is usually classified as convulsive or nonconvulsive in type.

Pernicious Vomiting—Although the etiology of pernicious vomiting of pregnancy is obscure, most authors classify the condition with toxemia. It has its inception in the first trimester, often shortly after the beginning of amenorrhea. In its milder form, the symptoms are anorexia, nausea and vomiting.

In the majority of cases of pernicious vomiting, which occurs in varying degrees of severity in about a third of all pregnant women, the symptoms can be controlled by adherence to a rigid regimen of dietary management consisting of small, dry feedings at four-hour intervals. The food should be high in carbohydrate value and bland in nature. Vitamin supplements, particularly those in the B group, are valuable since such a diet is usually deficient in vitamins. Fluids should be taken liberally between feedings. Often carbonated drinks are more readily tolerated than other fluids. Freedom from worry and household responsibilities and a rest period several times a day are advisable. Some mild sedative, such as phenobarbital or a bromide, may be used.

in sufficient amounts to effect relaxation. Treatment is much more effective when the patient is in the hospital.

If vomiting persists in spite of this management, severe hyperemesis may develop. Signs and symptoms of dehydration, hemoconcentration and vitamin deficiency are present. There is pallor, dry skin, salivation and rapid loss of weight and, as the condition progresses, there is often a rising pulse rate, slight fever and oliguria. Blood studies may show leukocytosis due to hemoconcentration with a low concentration of blood chlorides.

In severe cases of pernicious vomiting, jaundice, visual disturbances and polyneuritis may occur. These are grave complications and demand immediate treatment in the hospital. This provides an opportunity for enforcing complete bed rest and close observation and also facilitates laboratory studies. Treatment is directed toward combating dehydration, avitaminosis and acidosis. In the acutely ill patient this is probably best accomplished by means of intravenous infusions of 10 per cent glucose in physiologic saline solution. Of late years it has been our practice at the Clinic to fortify these solutions with injectable vitamin concentrates. Since a high carbohydrate intake further increases the demand for certain vitamins in the B group, particularly thiamine, the use of intravenous glucose might even enhance an impending deficiency state if vitamins were not supplied in adequate amounts. During the initial period of hospitalization it is often advantageous to discontinue the oral intake of all foods and fluids until the tendency toward vomiting actually has ceased. As previously mentioned, adequate fluid can be supplied by the intravenous route, or in some patients, by the rectal route, utilizing a solution of 5 per cent glucose or even by the subcutaneous route utilizing the continuous drip method. Sufficient sedation to keep the patient relaxed and slightly drowsy is beneficial. For this purpose, hypodermic injections of phenobarbital sodium, 2 grains (0.13 gm.), are effective.

After the nausea has been controlled, frequent small, dry feedings of bland foods again may be instituted and with improvement in the patient's condition, the diet may be increased in caloric content and volume in accordance with the patient's tolerance. Sedatives can then be given orally.

Several years ago reports appeared in the literature regarding the use of pyridoxine in the treatment of hyperemesis. This preparation has been used at the Clinic in both mild and severe cases of pernicious vomiting in doses of 50 mg. intravenously every one to three days, and in many cases the results apparently have been good. The frequency of its administration appears to vary considerably and we have relied largely on the patient's subjective symptoms and improvement in regulating the injections.

Therapeutic abortion for hyperemesis is rarely, if ever, a necessary part of treatment, since medical treatment including the use of in-

travenous glucose almost always maintains the patient in good condition until the process is corrected

Chronic Hypertension—Since chronic hypertension of itself is seldom an emergency condition unless it is complicated by some other disease, it will not be discussed in detail in this paper. This condition manifests itself by albuminuria and elevation of blood pressure. It antedates the pregnancy and therefore is evident on the first prenatal examination.

Preeclampsia—In its incipient form preeclampsia often is first recognized by a slight rise of blood pressure at the time of prenatal examination. It occurs in late pregnancy. A significant rise of the diastolic blood pressure is regarded by many physicians as a warning sign. It should be emphasized that a jump of twenty points in the blood pressure of a patient who previously had a low pressure is as significant as a similar change in a case in which the pressure was near the upper limits of so-called normal.

There may be rapid gain in weight, albuminuria and edema. Sometimes the first symptom is edema. If some edema occurs early in the course of pregnancy, toxemia is more likely to develop later than if edema is not present. Sudden increases in body weight are suggestive of fluid retention.

Rises in the level of serum sulfate often presage the onset of toxemia. At the Clinic this test is considered the most valuable of all blood chemistry determinations in cases of suspected preeclampsia. Ophthalmoscopic examination often reveals narrowing of the retinal arterioles of a spastic nature.

Patients who have evidences of incipient toxemia must be observed more closely than the average patient because of the possibility of progression of the process. Usually the patient may be up and about but rest periods in the morning and afternoon and limitation of activities are advisable.

Usually the use of some sedation in the form of a barbiturate, such as phenobarbital, $\frac{1}{2}$ to $1\frac{1}{2}$ grains (0.032 to 0.1 gm), three times a day, is instituted. The diet should be bland and low in carbohydrate value with optimal amounts of protein daily. The sodium ion should be eliminated from the diet as far as possible and the use of salt or baking soda should be avoided. In addition, 1,500 to 2,000 c.c. of fluids daily should be taken. If there is any edema that does not subside quickly on this management, ammonium nitrate or ammonium chloride in doses of 90 grains (6 gm) may be given. In a considerable number of cases at the Clinic the edema has subsided on this management, the blood pressure has lowered decidedly or at least remained stationary and the patient has been carried along to term and the spontaneous onset of labor.

If incipient toxemia does not respond satisfactorily or if the toxemia when first noted is severe, the patient should be hospitalized so that she can be watched closely and kept at complete rest in bed. The

presence of such subjective symptoms as persistent headaches, vertigo and nervous irritability often indicate that the patient should be observed in the hospital where a salt-free diet can be more closely administered. The intake of protein is kept at about 60 gm daily and fluids are given liberally. Ammonium nitrate, in the previously mentioned amount is continued and sedation is given to the point of effecting relaxation. The blood pressure is checked every two to four hours and the urine is examined daily to determine the degree of albuminuria. The daily weight, the twenty-four hour intake and output of fluid are recorded. If some improvement, such as decline in blood pressure, increase of urinary output to exceed the fluid intake and loss of weight and alleviation of subjective symptoms is evident, management can be continued status quo, until the fetus is viable. Regular ophthalmoscopic examination of the fundal vessels is also a valuable diagnostic aid in determining the patient's progress.

Since the likelihood of permanent vascular and renal damage increases in direct proportion to the duration of toxemia, one hesitates to carry such patients much past the time when induction of labor becomes feasible even though the toxemia may be under satisfactory control. If satisfactory progress is not made on the outlined regimen, the intravenous injection of glucose solutions is advisable. If 500 cc of a 10 per cent solution is not effective in producing diuresis, a 20 or even a 30 per cent solution can be used in smaller volume. The injections may be given two or three times daily.

If the progress of the patient is fairly satisfactory an effort should be made to carry her along until the period when the fetus might be viable and not too premature. The decision as to how long the pregnancy should be allowed to continue must be based on the understanding that prolonged toxemia increases the likelihood of permanent vascular damage. On the other hand, in view of our present knowledge concerning care of the premature infant, it is far better to have a premature baby than one dead or irreparably damaged by the effects of toxemia. Hence, management of this problem necessitates fine judgment, taking into consideration these factors plus the parity of the patient.

If in spite of treatment the toxemia becomes worse, this development often is manifested by an increase of headache, visual disturbances and sometimes epigastric pain. There is also a diminution of urinary excretion with increasing amounts of albumin. The values for serum sulfate and uric acid of the blood increase. The blood urea also may be slightly elevated. Twitching of the muscles and increased nervous irritability often are present and must be regarded as grave signs possibly indicating the approach of convulsions. Sedation with morphine sulfate, $\frac{1}{4}$ grain (0.016 gm) every four to six hours, then is indicated but care must be taken not to depress the respirations to less than eleven or twelve per minute.

Interruption of pregnancy is indicated if treatment is without results. The election of method for this procedure is largely dependent on the circumstances. In the case of a multiparous woman rupture of the membranes under aseptic precautions usually will suffice. In the case of a primipara with the cervix well effaced and the presenting part well engaged, this again may be the procedure of choice. If the cervix is not well effaced, the onset of labor may be hastened by the utilization of a large size Voorhees bag. The severe degree of morbidity often ascribed to this procedure has not been encountered at the Clinic and we still employ it on occasions. A simple expedient, one which possibly is not employed frequently enough in the type of case in which use of a bag is undesirable, is a Willett forceps. In the case of a primipara, with a high riding presenting part and a long, uneffaced cervix, it may be evident that the medical measures described previously for the induction of labor may consume a long time before delivery actually can be effected. In such cases and in those of cephalopelvic disproportion, cesarean section is the treatment of choice. However, it is well to recall that the patient is desperately ill and that a major surgical procedure carries with it a considerably increased risk.

Eclampsia.—The institution of prenatal care has led in general to early recognition, diagnosis and treatment of toxemia. As mentioned previously, if the condition cannot be controlled pregnancy can be interrupted before convulsions supervene. An occasional case is still encountered, however, in which the patient has not availed herself of prenatal care or in which, in spite of such care, sudden and fulminating toxemia with convulsions develops between prenatal visits. The convulsive state may develop first in the prepartum, intrapartum or immediate postpartum period, but regardless of time of occurrence, the plan of attack must be as follows: (1) control of the convulsion, (2) protection of the patient from injury and (3) elimination of toxic products from the body before considering the necessity for delivery.

The high mortality rate (20 to 30 per cent) which attended the now discarded methods of accouchement forcé or cesarean section in cases of convulsions show the fallacy of such management. A patient who is having or has had convulsions should be placed in a quiet, darkened room that is protected as much as possible from external noises. The bed should be provided with sideboards but otherwise no effort at restraint of the patient should be made. A padded tongue blade can be inserted between the molar teeth to prevent injury to the mouth and tongue during the convulsion.

In an effort to control the convulsions, an initial dose of $\frac{1}{4}$ grain (0.016 gm.) of morphine sulfate may be given and this may be repeated at intervals of one to four hours depending on the size of the patient and the severity of the seizure. The best guide to dosage is the respiratory rate which should not be depressed to less than 12 to 14 respirations per minute. The intravenous administration of magnesium

sulfate in 20 c.c. doses of a 10 per cent solution enhances the sedative effect of morphine by lessening nervous irritability and, in addition, stimulates the excretion of fluids from the body and thereby lessens edema. However, the amount of magnesium sulfate given must not exceed 6 gm. in twenty-four hours.

If the convulsions are not controlled by these sedative measures, a barbiturate may be given by intravenous injection. In our experience pentobarbital sodium has been satisfactory when carefully used. The inhalation methods of administering anesthetic agents should be avoided. After sedation has been effected, stimulation of diuresis and of elimination of toxins is advisable. Hypertonic solutions of glucose are efficacious, if the edema is severe, 250 c.c. of a 20 or 30 per cent solution may be utilized, but if the edema is slight, 1,000 c.c. of a 5 or 10 per cent solution may prove effective. The injections may be repeated three or four times in twenty-four hours or until diuresis is established. Improvement is evidenced by cessation of the convulsive seizures, diminution of the coma, diuresis and a warm, moist skin. After the convulsions have ceased the administration of oxygen through a nasal mask or if a mask is not available, a nasal catheter, helps considerably to counteract anoxemia. With the return of consciousness, sedation may be continued by the administration of drugs by the oral route, utilizing the barbiturates. In addition, water and fluids high in carbohydrate content, such as fruit juices, should be given by mouth, but the fluid intake must not greatly exceed the urinary output.

Fortunately a fair proportion of patients who have had convulsions go into labor spontaneously. However if this does not occur, sound medical reason dictates the initiation of labor as soon as the patient's condition has become stabilized.

HEMORRHAGE

Hemorrhage accounts for a major portion of the reported maternal mortality, as well as a high proportion of the medical emergencies encountered in this field. Hemorrhage may be divided roughly into two groups, namely, that which occurs in early pregnancy and that which occurs in late pregnancy. Postpartum hemorrhage also will be discussed.

Hemorrhage of Early Pregnancy—Most hemorrhages of early pregnancy are caused by abortion, ectopic pregnancy and hydatidiform mole in that order of frequency. In addition, cervical polypi, an anomalous uterine horn and carcinoma of the cervix also are causative factors, but their occurrence is so rare that discussion of them in this article does not seem justifiable. The reader therefore, is referred to any of the well-known textbooks on obstetrics.

The differential diagnosis usually can be made on the basis of the history and physical findings. In the case of *abortion* there is a history

of coitus followed by amenorrhea or at least some disturbance of menses. The symptoms commonly associated with early pregnancy, such as nausea, vomiting and soreness and engorgement of the breasts, may be present. The bleeding, which at first may be painless and slight, usually becomes increasingly severe and is associated with crampy pain in the mid-line. In the absence of infection the pain is intermittent in character. The presence of fever indicates that the condition is complicated by infection. Examination of the pelvis reveals that the uterus is softened and enlarged, usually in proportion to the period of amenorrhea, and the cervix is soft and patulous. If bits of decidua have been expelled, the diagnosis is more certain than otherwise.

In the case of *ectopic pregnancy*, the history of amenorrhea is usually not definite. The menstrual flow may have been scanty and the usual menstrual interval may have been disturbed. The symptoms of pregnancy often are indefinite. The bleeding is almost always associated with unilateral pain that is dull, boring and constant in nature. The pain often is aggravated by physical activity, straining at stool and movements of the uterine fundus. The classical picture of ruptured ectopic pregnancy is that of sudden, excruciating abdominal pain followed by signs of shock, collapse and hemorrhage out of proportion to the amount of external bleeding. On pelvic examination the uterus is enlarged and softened and shows signs of pregnancy but often the organ is not as large as would be anticipated from the period of amenorrhea. The cervix is firm and closed. There is usually a palpable fusiform mass in the adnexal region on the side of the greater pain. If an appreciable amount of intra-abdominal bleeding has occurred, the cul-de-sac feels full and doughy and may even bulge into the vagina. Often the rectus muscle on the side of the involved tube is definitely rigid. Cullen's sign, which consists of discoloration of the skin about the umbilicus, may be present.

In the case of *hydatidiform mole* the history of pregnancy is again present and the symptoms of early pregnancy such as nausea, vomiting and headache are often more pronounced than usual. The bleeding is usually scant at first, but may later become alarmingly severe. Pain is seldom a prominent symptom. A history of passage of cystic grape-like bits of tissue makes the diagnosis of hydatidiform mole more probable, especially if the uterus is extremely boggy and is considerably larger than would be expected for the period of gestation. If the patient can be observed for a short time, unusually rapid increase in size of the uterus makes the diagnosis more certain. Because of the great increase in gonadotropin the corpus luteum enlarges and may become cystic. Enlargement in the region of either ovary is an important contributory finding in diagnosis.

In most instances, the biologic tests, such as the Friedman test, are not of great value in the diagnosis of either abortion or extra-uterine

pregnancy for, while a positive test confirms the evidence of pregnancy, a negative test only points to the fact that the chorionic villi have been nonfunctional for a week to ten days regardless of whether their implantation is intra-uterine or extra-uterine. However, in the case of hydatidiform mole the fact that the test is strongly positive even in one tenth the usual dilution of urine is of considerable diagnostic value.

Hemorrhage of Late Pregnancy—In the latter half of pregnancy the principal causes of hemorrhage are placenta previa, premature separation of the normally implanted placenta and, more rarely, circumvallate placenta with premature separation.

In the case of *placenta previa* the history is that of sudden onset of painless vaginal bleeding. Although the bleeding may be profuse it is seldom fatal on first occurrence. Examination of the abdomen reveals that the uterus is relaxed and soft and that the presenting part is high and usually cannot be depressed into the pelvis. The fetal heart rate may be disturbed. If the emergency is not too acute, roentgenographic study of the placenta may reveal its location.

In the case of *premature separation of the placenta* a history of trauma to the uterus may be obtained. More than half of all cases of premature separation are associated with toxemia. The amount of external bleeding is dependent on the degree of separation and in mild cases the bleeding may be painless. At first there are usually intermittent painful contractions which soon become constant. The uterus becomes rigid and boardlike and is said to feel ligneous. The fetal heart rate is rapid, and if the separation is profound the heart tones may be absent. There is often a history of fetal activity followed by no fetal movement and it may be difficult to palpate the fetal parts. As the condition progresses the signs of blood loss are out of proportion to the external bleeding.

In the case of *circumvallate placenta* bleeding is an early symptom but it is usually scant. It is improved by bed rest but tends to recur on exercise. The hemorrhage is seldom severe enough to be considered an emergency unless the condition progresses to actual premature separation of the placenta.

The diagnosis usually must be confirmed by vaginal examination under sterile precautions. Such an examination must not be attempted until preparations have been made to proceed at once with the necessary treatment. Consequently this examination will be discussed more thoroughly in a subsequent section concerning treatment.

Postpartum Hemorrhage—Careful observation and measurement of blood loss during the third stage of labor and during the next twelve hours are essential. The average blood loss is between 250 and 300 c.c. and when the loss is in excess of 500 c.c. the danger limit is rapidly approaching. As the bleeding becomes excessive, symptoms of shock, such as rapid pulse, falling blood pressure, sighing respiration and cold,

clammy skin, follow rapidly. The causes of excessive blood loss in the postpartum period are partial separation of the placenta, retention of a fragment of placenta or succenturiate lobe, obstetrical lacerations and failure of the uterus to contract properly and to remain contracted.

Treatment—In all cases of hemorrhage treatment consists of hemostasis and replacement of lost fluids and blood. Management is specifically in accordance with the diagnosis but, in general when the condition is *ruptured ectopic pregnancy*, medical management or procrastination is seldom, if ever, justifiable. The necessary surgical measures to obtain hemostasis should be begun immediately. Any attempt at blood replacement usually is futile until the operation has been begun, but sometimes measures to combat severe shock are necessary during preoperative preparation of the patient.

If a diagnosis of *hydatidiform mole* is made dilatation and curettage or even hysterotomy to control bleeding usually is the best type of treatment. Fluid loss must be replaced. Because in about 3 per cent of all cases of hydatidiform mole, chorionepithelioma develops, the patient should be observed closely. The Friedman test should be repeated at intervals for a year or more and if abnormal bleeding again should occur, dilatation and curettage and microscopic examination of the scrapings should not be delayed.

In the treatment of cases of *abortion* my associates and I have adopted a conservative attitude. The majority of patients are regarded as potentially infected. The patient is kept at bed rest in a modified Fowler's position with ice caps to the lower part of the abdomen. Replacement of blood loss is undertaken by starting intravenous administration of 5 per cent glucose in physiologic saline, a solution of acacia, blood plasma or whole blood of the correct grouping, dependent on what the need may be. An oxytocic in the form of ergonovine, $\frac{1}{420}$ grain (0.0002 gm), is given every four hours for twenty-four hours as indicated. If bleeding is not controlled, 1 c.c. of obstetrical pituitrin (posterior pituitary extract) is injected intramuscularly. The pulse rate and blood pressure are checked at frequent intervals and the patient is observed closely for further excessive bleeding. If the patient is febrile, chemotherapy in adequate dosage is instituted. If rectal examination reveals products of conception incarcerated in the cervical os or in the vagina which cannot be expressed by bimanual pressure on the uterus, vaginal examination under sterile conditions is performed, removing the retained secundines manually or with an ovum forceps.

If hemorrhage persists in spite of these measures, curettage should be undertaken at once, utilizing a large blunt curet, or an ovum forceps. Our practice has been to conclude such a procedure by packing the uterus with a small amount of sterile gauze dusted with 5 gm. of sulfathiazole powder. The pack is allowed to remain in place from twenty-four to seventy-two hours. Bed rest is enforced until the

patient has remained afebrile for five days and the uterus is involuting satisfactorily. If infection is a complication, the period of bed rest is prolonged.

The plans for treatment of the patient who has prepartum hemorrhage usually are made at the time of vaginal examination and diagnosis. Therefore, as mentioned previously, the examination should never be attempted until all preparations have been made to proceed with whatever procedure may become necessary. In the meantime, infusions of plasma or whole blood are begun.

Treatment of *placenta previa* is dependent on the gravidity of the patient, the degree to which the placenta covers the cervical os and the patient's desire for a living infant. In all cases of central placenta previa in which there is a living child our treatment of choice is cesarean section.

In cases of incomplete placenta previa with the vertex presenting, the simplest measure is rupture of the membranes and slow release of a portion of the amniotic fluid. This is particularly applicable in the case of the multiparous woman but at times it is also effective in the primipara and is the only treatment necessary. The presenting part then descends, presses on the placenta and produces hemostasis. If this in itself does not suffice, a Willett forceps can be applied to the scalp and gentle traction applied. In selected cases in which these measures are not effective, insertion of the largest possible size hydrostatic bag has proved valuable although this increases somewhat the risk to the child. Braxton Hicks' version and bringing down one foot through the cervix so the thigh makes pressure on the placental site can be utilized when other measures fail. This is a fairly safe means of management for the mother, but the procedure is not so safe as far as the infant is concerned. It is particularly applicable if the fetus is not yet viable or is dead. Extraction should not be undertaken until the cervix has attained full dilatation. Manual dilatation of the cervix and forcible delivery have no place whatever in the management of cases of placenta previa.

In the case of *abruptio placentae* in a multipara who is near term and who has a soft dilatable cervix, medical management sometimes is satisfactory. The blood loss should be replaced and, after a sterile vaginal examination, the membranes should be stripped from about the internal os and ruptured artificially. This treatment is also applicable when the fetus is still and the separation has not become marked. However, if there is considerable separation and continued bleeding the procedure of choice is usually cesarean section. After delivery, regardless of the method used, the uterus is usually packed with several strips of iodoform gauze to prevent further loss of blood. If conservative measures do not control hemorrhage or if the uterine wall itself has been damaged by gross hemorrhage, hysterectomy becomes a necessity.

The same principles that apply in other cases of obstetric bleeding also apply to the management of *postpartum hemorrhage*. First, the cause of the hemorrhage must be accurately ascertained and corrected. A sterile vaginal examination is imperative. Vaginal lacerations or birth injuries to the cervix should be repaired. If the placenta has become partially separated and incarcerated, the uterine cavity is explored with the sterile gloved hand. The line of cleavage between placenta and uterus is found and with a sweeping motion of the hand the remainder of the placenta is separated and then extracted. Any fragments of retained placenta are removed in a similar manner. The uterine cavity is then firmly packed with sterile strips of iodoform gauze, tamponing them firmly into the fundus, cervix and apex of the vagina to insure their retention.

Oxytocics can be used in cases of atonic uterus, but if they do not rapidly produce hemostasis the uterus should be packed as previously described. Replacement of lost blood and fluids is important.

A few general statements regarding the replacement of lost fluids may be apropos. In general, replacement of fluids to a volume equal or nearly equal to the amount lost usually is desirable. This loss, as a rule, can be estimated fairly accurately. The replacement of fluids should be started early and should be rapid. Until fluids of more permanence can be obtained, infusion of saline or intravenous glucose can be started. Intravenous infusion of plasma or of a solution of acacia, which are now readily available commercially, is efficacious in combating shock.

There is, however, no really satisfactory substitute for transfusions of whole blood in the treatment of hemorrhage since there is depletion of cellular elements of the blood as well as of fluids. The blood should be of the proper group and preferably the blood of the donor and the recipient should be cross matched to avoid untoward reactions. In the light of recently acquired knowledge, determination of the Rh factor is also of importance in obstetric cases, and if any doubt about this factor exists, Rh negative blood should be used. In an effort to avoid an emergency and the resultant heavy drain of Rh negative blood from the blood bank, my associates and I have adopted the policy of obtaining an Rh determination and blood grouping on every obstetric patient at the time of admission for prenatal care. If an emergency should arise, information regarding the necessary blood type is readily available. If there is a long delay in obtaining properly grouped blood, infusions of blood plasma, which are often lifesaving, can be started. If every physician who cares for obstetric patients would obtain blood groupings and Rh determinations on six or eight healthy persons in his community who might act as donors, blood would be available in case of dire emergency and many a hemorrhaging woman might be saved who otherwise would be lost because of the delay in grouping donors.

INFECTIONS

Although much progress has been made in the management of infection, it is still one of the three main causes of maternal deaths. As in any infectious process, prophylaxis is most important. Such measures as careful rectal examination only when necessary to determine progress of a patient in active labor, vaginal examination only when necessary to obtain information as to progress which is not available on rectal examination, careful masking of the examiner and aseptic preparation of the patient help to reduce the incidence of infection. An elevation of temperature after delivery should be considered evidence of infection until proof to the contrary is obtained. Such causes for fever as engorged or caked breasts, appendicitis, pyelitis, cholecystitis and acute infection of the upper respiratory tract usually can be ruled out readily.

When the diagnosis has been established the patient should be isolated from other obstetric patients, preferably apart from the obstetric pavilion. The patient should be kept at complete bed rest in a modified Fowler's position with ice bags to the lower part of the abdomen. Positive fluid balance should be maintained. If this is impossible by the oral route, intravenous infusions of 5 per cent glucose in physiologic saline can be used. In the presence of anemia, transfusions of compatible blood are invaluable. Blood cultures and blood studies, including determination of the sedimentation rate, at frequent intervals are invaluable in determining progress of the condition. Chemotherapy in adequate dosage may be begun at once. After an initial small dose to determine any unusual sensitivity to the drug, the dose should be regulated by daily determinations of blood concentration so that an optimal level of the drug may be rapidly arrived at and maintained. If progress during the first forty-eight hours is unsatisfactory, penicillin should be used particularly if bacteriologic studies indicate the presence of an organism sensitive to this medication.

Either penicillin or chemotherapy in reduced dosage should be continued for several days after the patient has become afebrile. If the distention is severe, enemas can be utilized. If the upper part of the gastro-intestinal tract is involved the institution of drainage by use of a Wangensteen or a Miller-Abbott tube is of great value and should not be long delayed. Occasional careful examination of the pelvis will determine the presence of local abscess formation and the need for surgical drainage.

In the subacute stage conventional diathermy, given either through and through or by use of a vaginal applicator, hastens improvement of the patient's condition. Bed rest should be enforced until the patient has remained afebrile for at least a week to ten days and the sedimentation rate and white blood count have dropped to near normal levels. This conservative policy of medical treatment usually results in complete recovery and often, a return of childbearing function.

EMERGENCIES ASSOCIATED WITH THE THYMUS

ROGER L J KENNEDY AND GORDON B NEW

IN spite of the fact that proof that the thymus frequently exerts serious pressure upon the trachea is lacking and, despite the fact that the function of the thymus is still unknown, claims that it is a relatively frequent cause of alarming obstructive respiratory phenomena and of the sudden death of infants and children continue to be advanced. Proponents of these claims point chiefly to two pieces of evidence in support of their contentions: first, to the relief of symptoms that sometimes follows roentgenotherapy of the superior mediastinum, and second, to the finding of a large thymus in some infants and children who have died suddenly and unexpectedly.

These claims have been ably refuted by Morse,⁷ Hudson,⁴ Wilson¹¹ and other authors. The contention that some patients with stridor, dyspnea, cyanosis or other symptoms frequently improve after roentgen irradiation of the superior mediastinum does not constitute proof that they therefore suffered from enlargement of the thymus. Likewise, the finding of a large thymus at necropsy in cases in which patients have died suddenly is no proof that the thymus has been a causative factor in the death. The function of the thymus remains unknown, therefore, to invoke disturbed thymic function, a combination of disturbed thymic function and allergy or any other theory involving disturbed thymic function is unsupported by fact.

So far as the size of the thymus is concerned it should be recognized that there is considerable variation but that a thymus of considerable size is to be expected in any child who has not suffered from disease or inanition. Data published by Boyd,^{1, 2, 8} which deal with the size of the thymus during infancy and childhood, should be more widely perused. Familiarity with these data will tend to correct some of the current misconception regarding the size of the thymus.

Throughout the years that enlarged thymus and thymic death (including status thymicolymphaticus) have been debated, able investigators and clinicians have been found supporting opposite sides of the question. Even though one may be inclined to disregard the post hoc, ergo propter hoc reasoning of some who feel that the so-called thymic syndrome and so-called thymic deaths are real entities, one cannot ignore the opinions expressed by such competent and able observers as Jackson and Bowman,⁵ Wasson,¹⁰ Pancoast^{8, 9} and others who have expressed the opinion that they are something more than imaginary figments. However, neither they nor other proponents of the thymic syndrome and thymic death have offered proof that the thymus can exert pressure on the trachea that is sufficient to cause symptoms. The crux of the matter appears to rest on the diverse experiences of various

observers and the interpretations which they have chosen to place upon their observations. Experience at the Clinic seems uniformly to support the idea that neither concept can be supported by clinical or postmortem data.

Some years ago we⁶ reviewed the experiences of ten years in respect to the diagnosis of chronic stridor in childhood. At that time, it was pointed out that, in some cases of stridor in which a diagnosis of enlargement of the thymus had been made, examination revealed the presence of congenital relaxation of the larynx, cerebral palsy with congenital laryngeal stridor, laryngospasm, tracheal subglottic diaphragm, tumor of the thymus or multiple papillomas of the larynx. It was pointed out at the same time that, during the period in which these patients were observed, no child with symptoms referable to hypertrophy of the thymus and no death attributable to hypertrophy of the thymus were encountered. These observations included all deaths of newborn and older infants that occurred either spontaneously or during or following anesthesia. Since this report was made, our experience has not changed.

At the present time, it appears useless to attempt to dissuade the proponents of the theories of enlarged thymus and thymic death from expounding their beliefs before the medical profession and the laity. However, those physicians who have been unable to find factual support for these theories and those who have seen many instances in which an erroneous diagnosis of enlarged thymus was made in the case of a young person are entitled to hold the view that claims for the existence of these conditions are unfounded.

REPORT OF CASES

We shall report two interesting cases which show that not only may the diagnosis of enlarged thymus be erroneously made but that even when rather complete study and investigation have been carried out the true cause of dyspnea and stridor may be overlooked.

CASE I.—A boy aged eight weeks, was brought to the clinic on October 10, 1938. The family history was irrelevant. The patient had weighed 8 pounds (3.6 kg.) at birth and his delivery had been normal. He had nursed poorly and had had to be fed with a tube. He had been kept in the hospital for three weeks after birth. At the time of his dismissal, he had appeared to be in good physical condition.

Stridor developed when the child was five weeks of age. This increased in severity and dyspnea developed. The dyspnea became so severe that the accessory muscles of respiration were being used. When the child was brought to the Clinic, the stridor was chiefly inspiratory. The results of examination of the thorax were essentially negative. Laryngoscopic examination revealed some flabbiness of all of the supraglottic structures. The arytenoids were somewhat reddened. The child was placed in an oxygen tent but continued to have dyspnea and later cyanosis. Death took place three days after his admission. Although death from congenital relaxation of the larynx has not been encountered previously, it was thought that this was the cause of death in this case. However,

necropsy revealed a napkin ring like tumor in the subglottic region which on microscopic examination was found to be a hemangio-endothelioma.

CASE 2—A girl, aged nine weeks, was brought to the Clinic because of vomiting. The family history was irrelevant. For the first two weeks of life she had retained all feedings but had not gained any weight. She had had a peculiar wheezing respiration which had persisted. It occurred only intermittently when she was brought to the Clinic. Two weeks after birth she had begun to vomit. Emesis had become projectile. When she was seven weeks of age a Rammstedt operation had been performed. A thickened pylorus had been found. Emesis had continued after operation and there had been a progressive loss of weight. Roentgenograms of the thorax were essentially normal including the appearance of the heart and the region of the thymus gland. Roentgenographic examination showed a large stomach that was filled with gas. As cretinism was suspected, $\frac{1}{8}$ grain (0.008 gm) of thyroid was administered for a few days but did not produce any improvement.

The infant was greatly emaciated and weighed 2,870 gm. There were great irritability and hyperactivity. Respirations were grunting. Breath sounds were harsh in both lungs and bronchial in character over the apex of the right lung. There were numerous spots caused by thrush on the mucous membranes of the tongue and pharynx. There was evidence of some obstruction of respiration with inspiratory stridor. Laryngoscopic examination revealed an essentially normal larynx. The obstruction to respiration became more severe and an intratracheal tube was inserted. This produced an adequate airway but tracheotomy eventually became necessary. When the trachea was opened, some hard bloody crusts were coughed up and this enabled the baby to breathe easier. The surgical notes were as follows: "The obstruction is undoubtedly due to exudate in the trachea or bronchi." At the time the child was admitted to the hospital, a roentgenogram of the thorax showed some diminution in density of the right lung and partial atelectasis. The roentgenogram of the abdomen showed considerable gas throughout the intestinal tract. The pattern was not that of obstruction. A roentgenogram of the thorax made twenty days after her admission was normal. Temporary improvement followed supportive treatment, transfusions of blood and subcutaneous administration of fluids. Thirty days after her admission the temperature suddenly rose and death took place on the following day. Necropsy revealed a large cyst of the thyroglossal duct at the base of the tongue.

NONSURGICAL EMERGENCIES OF THE RESPIRATORY TRACT IN CHILDHOOD

GEORGE B. LOGAN

DIFFICULTY in breathing on the part of a child is always an alarming symptom and one that almost always demands prompt measures for relief. It may be due to interference with either inspiration or expiration or both and the cause may be disease of some part or parts of the tubular air passages or of the lungs.

Difficult inspiration is generally caused by disease of the larynx or adjacent structures which may be based on inflammation or presence of a membrane, tumor or foreign body. Infants and young children whose trachea and bronchi are of small caliber exhibit evidence of serious obstruction more readily than do older children and adults. The classical signs of laryngeal obstruction are retraction above the suprasternal notch and clavicles and of the epigastrium. Inspiratory stridor and retraction of the intercostal spaces are also often present.

CROUP

Spasmodic croup is one of the most common causes of inspiratory difficulty in young children. The onset is usually sudden and at night after the patient has been asleep for a time. However, symptoms may appear in the daytime. Croup may be preceded by an apparently mild infection of the respiratory tract. A harsh, brassy cough and inspiratory stridor are the initial symptoms. Some or all of the symptoms of laryngeal obstruction are usually present. The voice sounds become hoarse or disappear. There is rarely any associated fever. The symptoms, especially in young children, become progressively worse, but after several hours they generally subside spontaneously. They may, however, be relieved in a short time by the concomitant use of steam inhalations administered in a croup tent and antipyrine orally. Approximately 1 grain (0.065 gm) of antipyrine for each year of the child's age, to the age of five years, is a safe and effective dose. This may be repeated in an hour and at four hourly intervals thereafter, if necessary. The use of a teaspoonful of syrup of ipecac as an emetic is sometimes useful if the need for relief seems more urgent or if the steam inhalations fail to bring prompt relief. Bed rest in a room in which the atmosphere is warm and moist is advisable for a day or two after the initial attack since sometimes the difficulty recurs on one or more successive nights. Intubation or tracheotomy is practically never necessary.

LARYNGOTRACHEOBRONCHITIS

If the symptoms of croup are not alleviated after a few hours of treatment, the probability that they may be caused by acute laryngotracheobronchitis should be seriously considered. If this condition is

present, the dyspnea will persist or become progressively more severe. Fever and evidence of marked toxicity often appear early, especially if the patient is a small infant. The borderline between croup and acute laryngotracheobronchitis is not easily drawn.

Laryngotracheobronchitis is best treated in a hospital since tracheotomy or bronchoscopy or both frequently are necessary. High moisture content of the inspired air, which is best secured by use of a steam tent or a steam room, is essential. Oxygen should be well moistened, if its use becomes necessary, since unmoistened oxygen exerts an undesirable drying effect on the secretions of the respiratory tract. A water vaporizer may be used as an adjunct to the oxygen tent, as described by Davison. If this apparatus is not available, the oxygen may be moistened by suspending wet cloths in the ice compartment of the oxygen tent.* Steam may be run into the oxygen tent by pipe or rubber hose. This latter method, however, is cumbersome and not very satisfactory. The fluid intake should be kept at an adequate level. If the patient cannot take fluids by mouth, they should be given by the intravenous or subcutaneous route.

Sulfadiazine should be given in divided doses, about 1 to 2 grains (0.065 to 0.13 gm) per pound (0.5 kg) of body weight every twenty-four hours. The initial dose is best given by injecting it subcutaneously in the form of a 5 per cent solution of the sodium salt. Subcutaneous administration may be continued if the child refuses to take the drug by mouth. Regulation of the amount of sulfadiazine after the first twenty-four hours is determined by the patient's clinical course and the amount of the drug in the blood. If the child is able to take fluids by mouth, use of a saturated solution of sodium or potassium iodide is worth while as an additional means of keeping the secretions of the respiratory tract as fluid as possible. Five drops three times daily generally can be given to a child aged two years. The administration of atropine is contraindicated. The use of sedatives is generally inadvisable because such preparations may obscure the indications for tracheotomy. At the Clinic we prefer tracheotomy to intubation. The air entering the tracheotomy tube must be moist, this aids greatly in the prevention of crusts that tend to form in the trachea. The best apparatus for producing oxygenated vapor is a nebulizer which is attached to a tube that carries oxygen as described by Albers. In our experience, this measure has been lifesaving but this may not entirely obviate the need for bronchoscopic aspiration after

A small quantity of ice is left in the bottom of the ice compartment of a standard oxygen tent; this supply should be replenished frequently. A humidifier can be made by placing 8 to 10 inch legs under a shallow pan of water. A 10 inch handle is put over the top of the pan, over which can be suspended several lengths of gauze which dip into the water on the two sides. If gauze is unavailable, one or two wet bath towels, which must be moistened frequently are hung in the partially filled ice compartment. Boothby has estimated that this procedure will produce humidity of 70 to 80 per cent.

tracheotomy Bacteriologic examination of the tracheal secretions always should be made at the time of tracheotomy

DIPHTHERIA

Laryngeal diphtheria as a cause of inspiratory difficulty always should be considered If diphtheria of the nose or throat has been diagnosed, the laryngeal complication should be looked for In many instances the first sign of diphtheria is the insidious onset of croup which frequently occurs in the daytime The dyspnea is progressive and the nocturnal croupiness does not subside The voice sounds become hoarse and the child often becomes aphonic The previously described signs of laryngeal obstruction appear As the condition progresses, expiratory difficulty also may be noted In all cases in which diphtheria is suspected, swabbings of the throat should be cultured on appropriate media In many instances of laryngeal or tracheal diphtheria, cultures may fail to reveal *Corynebacterium diphtheriae* If the presence of diphtheric infection is suspected, diphtheria antitoxin should be administered without waiting for the results of the cultures

The same general plan of treatment as previously outlined for laryngotracheobronchitis may be used in the treatment of patients who have diphtheria of the larynx However, instead of the sulfonamides, diphtheria antitoxin should be administered as early as possible If the disease is mild or moderately severe from 20,000 to 40,000 units of antitoxin should be given If the patient is seriously ill from 40,000 to 80,000 units should be administered The intramuscular route is preferable but if the child is extremely ill the serum should be administered intravenously It is always wise to give what may appear to be an unnecessarily large dose rather than to give a dose that may be inadequate One large dose of antitoxin given early in the course of the disease should suffice, but it may be repeated in several hours if necessary Needless to say, sensitivity to the serum to be used should be determined by preliminary skin test or by the ophthalmic test If the results of these tests are positive, the usual precautions must be observed to prevent severe or serious reactions

The use of penicillin in the treatment of cases of diphtheria is still in the experimental stage but at present it does not appear to be effective

FOREIGN BODY, PAPILLOMA

A foreign body or an incarcerated pedunculated papilloma may be present in the larynx and produce signs of respiratory obstruction Diagnosis of such a condition may require direct laryngoscopic examination or possibly bronchoscopic examination Roentgenographic examination of the upper part of the respiratory tract may be helpful

ASTHMA

The most important cause of expiratory difficulty is asthma A feeling of tightness in the chest, dyspnea, wheezing and cough are its

most common symptoms. Auscultatory examination of the chest reveals sibilant and sonorous râles which are most notable during the expiratory phase. The expiratory phase of respiration is prolonged and the normal pause between inspiration and expiration is generally absent. Except during the initial attack, the diagnosis is frequently made by the parents.

The best drug for the immediate relief of an asthmatic attack is epinephrine (adrenalin chloride). An aqueous solution of 1:1,000 is administered subcutaneously. It is rarely necessary to give a child a dose greater than 0.5 c.c. Several small doses at intervals are more effective and better tolerated than a single large dose. The drug also may be administered in peanut oil or in a gelatin mixture, the dose being the same as of the aqueous solution. The theoretical advantages of the peanut oil or gelatin preparation are slowness of absorption and relatively prolonged action. The oil preparation however often fails to exhibit these advantages and furthermore the oil itself occasionally causes allergic reactions.

Epinephrine also may be administered in a 1:100 solution by means of a nebulizer. A few drops of the solution are placed in the all-glass or plastic nebulizer, which is a special type of atomizer, the nozzle is directed down the patient's throat, and the bulb is squeezed as the patient inspires. One or two squeezes during each of three to five inspirations will generally suffice. For small children the nebulizer can be operated by an adult; older children learn easily to use it themselves. Untoward reactions to epinephrine are rarely seen even when the drug is used repeatedly in this manner.

Ephedrine hydrochloride or sulfate, which is given in capsule form by mouth, is often effective in controlling asthmatic attacks. It may be given to small children as a powder in syrup or jelly. The dose for older children is $\frac{3}{8}$ grain (0.024 gm.) for younger children, $\frac{3}{16}$ grain (0.012 gm.) or less may be effective. One-half to $\frac{3}{4}$ grain (0.032 to 0.05 gm.) of one of the barbiturates is administered concomitantly to combat the stimulating effect of the ephedrine as well as to calm the patient.

Propadrine hydrochloride (di-phenyl-1-amino-2-propanol-1-hydrochloride) $\frac{1}{10}$ to $\frac{1}{4}$ grain (0.012 to 0.050 gm.) orally every three or four hours may be tried. This drug is considered by some authors to produce fewer untoward reactions than does ephedrine.

Aminophylline may be used orally, rectally or intravenously. It is of value for patients who do not react favorably to epinephrine. Some authors consider aminophylline more useful in the prolonged attack than in the acute attack. I have found that it may be of value in both conditions. Several commercial preparations of the drug are designed for oral use are available in either the pure form with a barbiturate or with a barbiturate and ephedrine.

Suppositories of aminophylline combined with one

rates in a cocoa butter base are frequently useful. The action of the drug when it is so administered is slower but somewhat more prolonged than when given orally or intravenously. Aminophylline, $3\frac{3}{4}$ grains (0.25 gm), together with seconal sodium (sodium propylmethylcarbonylallylbarbiturate), $\frac{3}{4}$ grain (0.05 gm), may be given in this manner to children, aged two to ten years. Older children may require 5 to 7 grains (0.3 to 0.45 gm) of aminophylline. The drug also may be given in solution by rectal instillation. This mode of administration produces rectal irritation in some cases.

The intravenous administration of aminophylline produces a prompter effect than oral or rectal administration, however, it is important that it be given slowly. The dose for a ten year old child is $3\frac{3}{4}$ grains (0.25 gm), about half this dose is given to small children. Aminophylline when given intravenously often is combined with glucose. Patients who have severe asthmatic attacks benefit from the intravenous administration of 100 to 300 c.c. of a 25 per cent solution of glucose. Larger amounts of a 10 per cent solution also are often effective.

Theophylline is combined with one of the barbiturates in one commercial preparation for oral use. In our experience at the Clinic, this preparation at times has proved beneficial.

The use of sodium or potassium iodide is of value especially in the treatment of prolonged attacks of asthma and as an aid in prevention. At the Clinic we use the saturated aqueous solution since variation of the dose can be made with ease and accuracy. The dose is varied according to age and degree of asthmatic difficulty, 5 drops three times daily being given to a child, aged four years. Older children who have severe asthma may be given 25 to 30 drops three times daily.

Oxygen administered in a tent or by mask is sometimes helpful. The combination of 80 per cent oxygen and 20 per cent helium is frequently very effective. Since this mixture is best given by mask, its use unfortunately is limited to those children who will tolerate a mask and for whom a small size mask can be secured. The administration of such an oxygen-helium mixture in a tent is not completely successful unless the tent is practically airtight.

In the treatment of patients who have status asthmaticus, the rectal administration of ether in oil is a useful procedure. Three to 4 ounces of ether mixed with an equal amount of warmed olive oil is instilled through a small rubber catheter. An amount smaller than the initial dose may have to be repeated at intervals of a few hours for twenty-four hours.

PNEUMONIA

Pneumonic processes may produce dyspnea which is not attributable to obstruction. The cause seems to be a combination of pain, toxicity and reduced vital capacity. Space does not permit detailed discussion of the different types of pneumonia.

The onset of primary or lobar pneumonia is characterized by fever, dyspnea and cough. The child's face is flushed, the ala nasi dilate with each inspiration and the respiratory rate is increased. This chain of events generally follows mild infection of the upper part of the respiratory tract. Children between the ages of about two and fourteen years who suffer from this type of pneumonia generally make a satisfactory recovery. The use of the sulfonamide compounds has lowered the already low mortality figures and also has decreased the morbidity. Their use in adequate dosage, that is, 1 grain (0.065 gm) per pound (0.5 kg) of body weight in twenty-four hours, therefore, is worth while. One-third to one-half of the drug is given as an initial dose and one-fourth of the twenty-four-hour dose is then given every six hours. The sulfonamide compound may be administered in a 0.5 or 5 per cent solution subcutaneously if necessary. Its use is continued for forty-eight hours after the temperature is normal and then often in half the usual amount for one or two days. Sulfadiazine is the current choice of these preparations.

The patient's fluid intake should be sufficient so that the urinary excretion remains adequate. The minimal intake of an infant should be 1,000 c.c. of fluid and that of a twelve to fourteen year old child should be 2,000 c.c. The diet should be as nearly normal as the patient will take. A daily bowel movement is desirable, chiefly because abdominal distention often develops in association with pneumonia. A daily enema may be necessary in the early part of the disease. A mild laxative such as milk of magnesia is often useful. When dyspnea is marked or when cyanosis occurs the administration of oxygen is indicated.

BRONCHOPNEUMONIA

Bronchopneumonia is the most serious type of pneumonia of infants and young children. It may complicate communicable diseases such as measles, or it may be secondary to infection of the respiratory tract. Fever and cough are often the chief symptoms. Dyspnea may be absent or marked, it is generally marked in infants. The disease may be acute and overwhelming, especially in poorly nourished infants or in those who are convalescing from other diseases.

The treatment is essentially the same as that outlined for primary pneumonia. The use of oxygen is often necessary early in the course of the disease. Transfusions of small amounts of blood are sometimes helpful, especially in the case of a debilitated infant, if the procedure can be carried out without excessive pain or discomfort.

One form of bronchopneumonia has been termed "capillary bronchitis" by many authors because of the predominant involvement of the terminal bronchioles. Auscultation reveals many fine râles in part or all of the lungs. Dyspnea is severe and sometimes cyanosis occurs. Although many clinicians have abandoned the use of the mustard pack at the Clinic we continue to find it effective in this type of case.

A double handful of mustard is placed in a dishpan of water. This mixture is stirred and heated slowly until the fumes become irritating to the eyes. Then the pan containing the mixture is removed from the stove. A small blanket is soaked in the solution and then wrung partly dry. The patient is wrapped in this, care being taken to see that the blanket is wrapped completely around the arms and legs as well as around the body, covering the body from the neck down to and including the feet. The patient is covered with a dry blanket and allowed to remain in this pack for one-half to three-fourths of an hour or until the skin becomes pink. The patient then is removed from the moist blanket and wrapped in a warm blanket with a hot water bottle placed at the feet and allowed to remain in this warm dry pack for another hour. While the pack is being applied, the patient should be given cool water or other cool drink.

The remainder of the treatment is the same as for other types of pneumonia. The recommendations previously made for prevention of drying of secretions in the respiratory tract in the presence of laryngotracheobronchitis are often applicable to this type of case.

CARDIAC EMERGENCIES IN PEDIATRIC PRACTICE

HADDOW M. KEITH

THERE are relatively few times when heart disease is severe and acute enough to be called an emergency. The following five conditions may be included in this category: (1) direct trauma, (2) asthma accompanied by heart disease, (3) pericardial effusion, (4) acute cardiac failure and (5) paroxysmal tachycardia.

DIRECT TRAUMA

Direct trauma is rare and is due to bullet wound or penetration by a sharp object. Treatment is essentially surgical with suturing of the heart muscle if possible and supportive treatment with transfusions of blood and infusions of solution of glucose or of glucose and sodium chloride.

ASTHMA ACCOMPANIED BY HEART DISEASE

In the presence of acute or chronic cardiac disease, the occurrence of an asthmatic attack may precipitate an emergency. Rapid relief of the asthmatic attack may be obtained by means of epinephrine administered subcutaneously. Cyanosis and in particular, dyspnea may be relieved by placing the patient in a helium-oxygen or oxygen tent. The effect of epinephrine may be prolonged by the use of ephedrine. Absolute rest in bed is, of course, essential and morphine may be of great help in keeping the patient as quiet and comfortable as possible. Aminophylline may also be used intravenously, $3\frac{3}{4}$ grains (0.25 gm.) being given to a child of six to ten years. (See emergency treatment of asthma.)

PERICARDIAL EFFUSION

Pericardial effusion is fairly common among children and may at times constitute an emergency. It is usually due to an acute infection of the pericardium with much sepsis and toxicity. In addition, much of the distress is due to the so-called tamponade of a large collection of fluid including hemopericardium. Willis² stated that in approximately 68 per cent of all cases pericardial effusion is due to the acute infectious type of disease and that it occurs secondarily to other intrathoracic infections: pneumonia, empyema, mediastinitis, acute non-tuberculous pleuritis and pulmonary abscesses. In rare cases it may be secondary to a puncture wound, rupture of a subdiaphragmatic abscess into the pericardium and so forth. It may also be the result of foci of infection in other parts of the body and may follow scarlet fever, typhoid fever and so forth.

The diagnosis of acute pericarditis when the patient is a child is not always simple and it is particularly difficult when the patient is an

infant A friction rub may be audible but with the rapid collection of fluid this may not be present When children have pneumonia or other acute infection, acute pericarditis may be kept in mind as a complication In such cases sudden embarrassment of the circulation with some muffling of the heart sounds and increase in the cardiac dullness, both to right and to left, is suggestive The apical impulse may become feeble and diffuse but the pulse may remain strong in spite of the diminished intensity of the cardiac sounds Dullness with evident bronchial breathing may be present at the angle of the left scapula Roentgenoscopic examination may be helpful, revealing the large globular or "onion" shaped heart with absence of pulsations of the margins Fever and leukocytosis may persist with improvement in, or disappearance of, the primary infection Further evidence in favor of a large effusion is increase of venous pressure, with, possibly, enlargement of the liver

In addition to acute purulent pericarditis the tamponade effect may occasionally be produced suddenly in acute fibrinous pericarditis and even less frequently in tuberculous pericarditis The symptoms and signs are much the same as in purulent pericarditis, with the exception that evidence of other acute infection may be lacking in the fibrinous form and will be lacking in the tuberculous type

Treatment—When this condition becomes an emergency, immediate treatment by paracentesis of the pericardium or, in certain cases, cardiolysis will relieve the patient at once These are surgical procedures, the technic of which will not be described here Morphine may be used in sufficient amount to insure adequate rest When there is definite purulent infection, sulfadiazine may be given intravenously or by mouth in sufficient amount to maintain the blood level between 15 and 25 mg per 100 c c of blood or penicillin may be used

Rheumatic pericardial effusions usually subside spontaneously and rarely require paracentesis

In cases of tuberculous pericarditis, temporary relief from the tamponade effect may also be given by paracentesis

ACUTE CARDIAC FAILURE

Acute myocarditis with failure may be present as an emergency Such a patient is restless and in great distress, with dyspnea, cyanosis, enlargement of the heart and all the evidences of congestive failure, for example enlarged liver, moisture in the lungs, pleural effusion, ascites or edema He will prefer to be propped up in an almost vertical position or leaning forward on a firm support

My colleagues and I recently had occasion to treat such a patient (a boy of seven years) He was kept in an oxygen tent for forty-eight hours and was given three ampules (2 c c each) of digifolin intravenously in the first twenty-four hours One-sixth grain (0.01 gm) of morphine sulfate was given at once and followed by $\frac{1}{12}$ grain

(0.0054 gm.) when necessary. A transfusion of 125 c c of whole blood was given slowly, followed by a slow intravenous drip of 1,000 c c of 10 per cent solution of glucose.

On the third day the oral administration of $1\frac{1}{2}$ grains (0.1 gm.) of digifortis was begun and was continued daily until the twenty-first day. After this all medication was discontinued and the patient made an apparently complete recovery.

PAROXYSMAL AURICULAR TACHYCARDIA

Paroxysmal auricular tachycardia is rare in children but may be successfully treated. In 1942 a twenty months old baby was admitted to the hospital because of a very rapid heart rate. No etiologic factor could be determined. Three weeks previously he had had a similar attack. The electrocardiogram showed evidence of auricular flutter, the heart rate being 258 beats per minute. The patient was given intravenously 1 c c of cedilanid (lanatosid-C) containing 0.2 mg. or 0.8 cat unit per cubic centimeter and this was repeated in one hour. Three hours later the heart rate was approximately 130 beats per minute and the patient appeared well. This is in agreement with the experience of Hubbard¹.

MANAGEMENT OF NONSURGICAL EMERGENCIES ASSOCIATED WITH THE URINARY TRACT OF CHILDREN

ROGER L J KENNEDY

MANY emergencies due to conditions in the urinary tract of children are essentially urologic or surgical problems. The physician, however, must possess a knowledge of the procedures necessary for their recognition and treatment.

A sudden sharp reduction in the amount of urine excreted by an infant or child calls for immediate consideration of its cause. Conditions, such as obstruction of the posterior urethra and vesical neck or obstruction due to calculi or neoplasms can usually be ruled out by the history, physical examination and catheterization or, if it is necessary, by cystoscopic examination. Likewise, inability to urinate may be due to neurologic disturbances, such as traumatic, inflammatory or neoplastic myelitis, but the cause in such cases should be evident. The finding of an overdistended bladder furnishes evidence that the anuria or oliguria is probably not dependent on inability of the kidneys to secrete urine. The conditions just mentioned cannot be considered strictly medical emergencies and, therefore, will not be considered here.

Occasionally a medical problem involving other systems or organs of the body may account for marked decrease in the output of urine. Cardiac decompensation which is discussed elsewhere in this volume is an example of such a condition.

In the infant or young child particularly, dehydration resulting from diarrhea or vomiting may require special treatment to overcome the gastro-intestinal disturbance and incidentally to restore sufficient fluid to the patient in order to re-establish renal excretion. Occasionally anuria or oliguria may be due to thrombosis of the renal veins. Although there is no effective treatment for this condition its presence may be suspected if abdominal pain and hematuria have been followed by cessation of the secretion of urine and frequently by the passage of clots of blood.

Transfusion reactions too occasionally are the cause of suppressed renal function.

NEPHRITIS, NEPHROSIS AND CERTAIN OTHER CONDITIONS

After exclusion of the conditions considered thus far the chief problem in the management of medical emergencies associated with the urinary tract of children is the determination of the type of renal disease that is accountable for the decreased output of urine. If oliguria manifests itself during or shortly after an acute infectious disease, such as tonsillitis, scarlet fever or pneumonia, the probability that acute

nephritis is present, becomes great. If other symptoms, such as edema of the face and ankles, slight or moderate elevation of blood pressure and, if sufficient urine is obtainable for examination, albuminuria and hematuria, are found, the diagnosis becomes practically certain. Although more complicated chemical analyses, such as the determination of the value for blood urea, may tend to confirm the diagnosis, they usually are not necessary.

Faced with such a situation, the physician will do well to explain to the parents that the outlook in such cases is generally good and that the condition tends to correct itself even in the absence of any therapeutic measures. While it has been customary to reduce the amount of protein in the diet to about a gram of protein per kilogram of body weight per twenty-four hours and to decrease the allowance of salt and liquids, it is questionable whether such measures are imperative or even necessary. The question as to the degree to which liquids need be restricted has received a good deal of attention in the past. It is now generally agreed that the amount of liquid permitted may be governed by the desire of the individual patient. If the oliguria persists or anuria develops, an attempt to establish diuresis may be made by the intravenous injection of 100 to 300 c.c. of an 8 per cent solution of sucrose. The use of mercurial diuretics in such cases usually is contraindicated.

The necessity for inducing diuresis may become especially urgent if convulsions (thought to be due to edema of the brain) occur. An attempt then may be made to induce diuresis either by the use of sucrose as just mentioned or by the intramuscular injection of magnesium sulfate. The dose of magnesium sulfate may be 0.2 gm. per kilogram of body weight in a 10 or 25 per cent solution. The injection may be repeated once or twice.

Occasionally, particularly at its outset, acute diffuse pyelonephritis may be accompanied by suppression of the renal function sufficient to cause anuria or marked oliguria. It is important to overcome this condition as promptly as possible. The intravenous administration of an 8 per cent solution of sucrose in half strength Ringer's solution may bring about desired diuresis.

Oliguria or anuria may develop during the course of so-called nephrosis which in its typical form is characterized by edema, anasarca, albuminuria, the appearance of doubly refractive bodies in the urine and by elevation of the serum lipids. In my experience this disease in its pure form is seldom encountered in children except at the onset. Some time during the disease erythrocytes appear in the urine and retention of nonprotein nitrogen in the blood takes place. These findings indicate that nephritis is present. With the development of oliguria and anuria the edema and the ascites increase concomitantly and sometimes hydrothorax develops. The prevention of anuria or oliguria and the concomitant prevention of increasing retention of water are thought to be favored by a diet which contains 2.5 to 3 gm. of protein

per kilogram of estimated body weight for twenty-four hours and the elimination of nearly all the salt (not more than 2 gm of salt daily)

If anuria or oliguria develops in spite of these measures, one or more of the following measures may be employed. Thyroid extract may be administered. In the beginning the dose is 1 grain (0.065 gm) daily, this is increased at intervals of three to four days by 1 grain (0.065 gm) until 6 (0.4 gm) or more grains are given each day or until diuresis or diarrhea occur. Potassium nitrate may be given in doses of 10 to 15 grains (0.65 to 1 gm) three times daily to a child three years of age. This amount may be increased to 15 or 30 grains (1 to 2 gm) three times a day. Ammonium chloride also may be tried. The initial dose may be 5 grains (0.3 gm) three times a day and this may be increased gradually until the pH of the urine is 5.0 (tested with nitrazine paper). The administration of urea by mouth also may be employed. The dose is 20 to 100 gm daily. The diuretics, such as theobromine, theophylline, theocalcin, theocin and aminophylline, occasionally seem to be effective. If the mercurial diuretics, such as salyrgan or mercupurin, are used, the initial dose should be small. The initial dose of salyrgan may be 0.25 cc given intramuscularly. After this dose has been given, signs of renal irritation (hematuria) should be looked for. If none are evident after two or three days, 0.5 cc may be given. With this care the dose may be increased gradually to 2 cc. If diuresis does not occur after the injection of 2 cc, use of the drug should be discontinued. A similar plan should be used if mercupurin is employed. Intravenous transfusions and infusions have been employed with variable results. Fairly large transfusions of whole blood (20 to 30 cc per kilogram of body weight or 10 to 15 cc per pound of body weight) may be given and should be repeated at relatively frequent intervals. Plasma may be used in place of whole blood. Lyophil serum in a concentration of 4:1 has been used successfully but I have observed some undesirable reactions following its use.

A not uncommon development during nephrosis is peritonitis or the so-called peritoneal syndrome characterized by fever, abdominal pain and tenderness. The use of sulfonamides, preferably sulfadiazine, is indicated and effective in the control of this condition. If the blood urea is elevated, care must be observed to avoid undesirably high concentrations of the drug in the blood. Since the infecting organism is most commonly pneumococci (less frequently streptococci), penicillin may be tried in place of the sulfonamides. To date I have had no experience with penicillin in treating this syndrome.

Another condition that may develop in nephrosis is the so-called erysipeloid lesion which, as the name implies, is a condition of the skin similar to, and possibly identical with, erysipelas. Sulfonamides, penicillin and in some cases, anti-scarlatinae streptococcal serum may be used in treatment.

COMPLICATION OF TREATMENT WITH SULFONAMIDES

From an early period in the use of the sulfonamides it has been recognized that their use may be followed by the accumulation of large numbers of crystals in the kidneys with consequent obstruction in the ureter, renal pelvis or tubules. Not infrequently this reaction is accompanied by renal colic. Prompt discontinuance of doses of the drug and oral and intravenous administration of large amounts of fluid usually re-establish the flow of urine but sometimes irrigation of the renal pelvis and ureters is necessary. The occurrence of this condition does not necessitate the permanent discontinuance of the use of sulfonamides but requires that they be given in smaller amounts with careful observation to make sure that sufficient urine is excreted and that the level of the drug in the blood does not become excessive. The concomitant administration of alkali in the form of sodium bicarbonate is thought by some physicians to decrease the possibility of the development of this undesirable condition.

CERTAIN MECHANICAL OBSTRUCTIONS IN THE URINARY TRACT

Mechanical obstructions may occur in the urinary tract which do not call for the services of the urologist or surgeon. Ulceration at the external urethral meatus and of the surrounding glans penis in the male may cause acute retention of urine. The use of compresses moistened in warm solution of boric acid will usually soften the crust which may be removed and allow the urine to be expelled. A similar condition may develop when a redundant prepuce becomes inflamed. Either the resultant discomfort occasioned by urination or occlusion by inflammatory reaction may account for the retention. Again the application of warm wet boric acid compresses may be sufficient to relieve the condition, at least temporarily. Subsequent circumcision is usually indicated.

Paraphimosis due to constriction of the retracted prepuce and consequent edema may be sufficiently marked to interfere with urination. The accepted procedure in such cases is the application of an ice cap or cracked ice wrapped in several layers of cotton material. After a few hours of such application the edema usually has subsided enough so that the prepuce may be drawn forward over the glans. Then the residual edema can disappear. Occasionally a dorsal slit through the redundant portion of the prepuce and the constricting band may be necessary for relief. An incident of this sort is usually considered an indication for subsequent circumcision.

ACUTE NONSURGICAL EMERGENCIES RELATED TO THE GASTRO-INTESTINAL TRACT

GEORGE B LOGAN

ABDOMINAL pain, vomiting, diarrhea and evidence of gastro-intestinal bleeding are symptoms for which urgent medical attention is often sought. These symptoms may occur singly or in varying combinations. Certain of the disease conditions which cause these symptoms in infancy and childhood will be discussed.

Some of these symptoms are the result of conditions which are treated surgically. However, the diagnosis of the condition and the decision as to the need of surgical care must be made by the physician who first sees the patient.

The ingestion of poisons will be dealt with only briefly in this paper.

COLIC

Colic, strictly speaking, refers to any acute abdominal pain. In pediatric practice the unqualified term generally is used to denote the presumed recurrent abdominal pain observed in many infants. The word "presumed" is used advisedly since when an infant has recurring spells of crying in which he flexes his thighs on his abdomen this act is interpreted as indicating the presence of acute abdominal pain. This interpretation undoubtedly is often correct. However, there is some evidence that hard crying in early infancy is a reaction to other stimuli. My associate, Dr C A Aldrich, has said that it is more properly termed "compulsion crying." As the infant matures the compulsion crying stops. This is to be expected at the age of about three months. The so-called three month colic may be explained in this way.

Further discussion of the etiology and pathogenesis of colic would be in the realm of individual speculation and experience. The incomplete raising of air swallowed during the course of feeding, intolerance to certain foods and fatigue have all been individually or collectively found to be important.

There seems to be a higher incidence of colic among the infants of constitutionally nervous or high strung parents than among those of a more phlegmatic nature.

The crying spells may occur at a regular time of the day such as early evening or 2 to 3 a m, or they may occur at intervals throughout the twenty-four hour period. The grandmother or mother usually makes the diagnosis and the physician is summoned only when the use of various home remedies has failed. It is the physician's first duty to ascertain that no organic cause for the colic, such as intussusception or incarcerated hernia, is present. Gentle rubbing of the abdomen, the application of heat and an enema generally will relieve

the immediate situation. The use of phenobarbital, $\frac{1}{8}$ to $\frac{1}{4}$ grain (0.008 to 0.016 gm.), or a few drops of camphorated tincture of opium may be necessary. Atropine sulfate, 1 to 3 minims of a 1:1,000 aqueous solution, often is helpful. Various carminatives such as soda mint, cinnamon water and peppermint water have been used.

As a means of preventing further attacks the various etiologic factors previously mentioned should be investigated. Some infants do not tolerate orange juice. A daily dose of 25 mg. of ascorbic acid is an effective substitute. A change of formula, if the infant is not breast fed, might be tried. Suggested changes are trial of another carbohydrate, evaporated milk, acidified milk or protein milk. It is unwise, however, to make frequent changes of formula. In the rare instance of persistent and uncontrolled crying it is necessary to hospitalize the infant so that the mother and other members of the family can get some rest.

APPENDICITIS

The diagnosis of acute appendicitis is often difficult. The so-called classic symptoms of the disease, that is, generalized abdominal or epigastric pain migrating to the right lower quadrant of the abdomen, nausea and often vomiting and slight elevation of temperature, frequently do not all occur together.

In the case of a child, abdominal pain, especially if located in the right lower quadrant, should always suggest appendicitis regardless of whether it is associated with nausea, vomiting, diarrhea or fever. The most reliable sign is local tenderness over McBurney's point. Muscle spasm, rebound tenderness and tenderness on the right when a rectal examination is performed may or may not be present. The indiscriminate removal of the appendix of every child who has abdominal pain is not advisable but if tenderness in the right lower quadrant of the abdomen can be demonstrated the wisest procedure is appendectomy.

The leukocytes often are increased in patients who have acute appendicitis and there is an actual increase of the neutrophilic polymorphonuclear cells. However, the leukocyte count may not be elevated. This blood examination should be used as a minor rather than as a major diagnostic aid in helping to confirm the clinical diagnosis.

A child who has pneumonia may have abdominal pain as an initial complaint. There may be no physical or roentgenologic signs of the pneumonic process. Fever is usually present. The leukocyte count often is elevated to 20,000 or 40,000 cells per cubic millimeter of blood, which is unusually high for the onset of acute appendicitis. The superficial abdominal tenderness noted in pneumonia is not increased by deep palpation. Rectal tenderness is not elicited in the presence of pneumonia. In a few instances it has been impossible to distinguish between appendicitis and the abdominal pain associated with pneumonia. Occasionally the two conditions coexist. When real

doubt exists as to which disease is present it is better to remove a normal appendix from a child who has pneumonia than to allow an appendix to rupture in a child presumed to have pneumonia

INTUSSUSCEPTION

Intussusception is a condition for which surgical treatment is urgent. Therefore, an early, accurate diagnosis should be made. Children of any age may have this condition but it is more common in those less than two years of age. The most characteristic symptom of intussusception is recurrent cramping abdominal pain. The pain generally occurs regularly at intervals of a few minutes. Sometimes the recurrent pain is noted for one or more hours and then ceases for several hours. Infants manifest the pains by crying spells. An abdominal mass and rectal bleeding eventually are noted. It is better to make the diagnosis before this occurs.

Many instances have been reported in which intussusception inadvertently or intentionally was reduced by a barium enema given under the fluoroscope. If good surgical help is available, such a procedure is inadvisable. The pressure of the enema may not be well controlled and the condition of the bowel wall cannot be seen. If the enema fails to reduce the intussusception, operation has been that much longer delayed.

ANAPHYLACTOID OR HENOC'S PURPURA

The onset of this condition is generally acute. The abdominal tenderness and pain may be either generalized or localized. Evidence of intestinal obstruction generally does not occur. Either vomiting or diarrhea or both may be present. One is aided in making the diagnosis if purpuric skin manifestations occur or if there is blood in the stool or vomitus. In some instances, purpuric lesions may be seen in the mucosa of the rectum and sigmoid at the time of proctoscopy. The abdominal pain, however, may be present for as long as seven days before any purpuric manifestations appear. In this type of purpura, the blood platelets are present in normal number and the bleeding and coagulation factors of the blood are normal. The Rumpel-Leede test is often positive. Sensitivity to food or other substances is considered by some authors as an etiologic factor.

Treatment is not satisfactory. There may be one or more recurrences of the disease. The initial attack may last several weeks with exacerbations and remissions. Acute nephritis or cerebral hemorrhage may occur as a complication. Edema involving the face and scalp, extremities and genitalia may be noted for short periods.

Blood transfusions may help. The use of moccasin snake venom has been recommended but its use may be attended by some unpleasant reactions. The abdominal pain may be controlled by the use of a hot water bottle but codeine, $\frac{1}{2}$ to 1 grain (0.032 to 0.065 gm), morphine

sulfate, $\frac{1}{16}$ to $\frac{1}{8}$ grain (0.004 to 0.008 gm) or demerol (1-methyl 4-phenyl piperidine 4-carboxylic acid ethyl ester hydrochloride) 50 to 100 mg, often are necessary. Small doses (0.25 cc) of epinephrine chloride in 1:1,000 aqueous solution given subcutaneously at frequent intervals sometimes have been beneficial. The use of the same drug in oil or gelatin also may be tried. The administration of ascorbic acid (100 to 300 mg daily) vitamin P (citrin) and vitamin K (5 to 40 mg daily) have been suggested, as well as calcium lactate and salicylates. In severe cases there may be considerable weight loss. The use of parenteral fluids may be necessary. Small frequent feedings often are tolerated better than the customary three meals a day. Skin tests for sensitivity to various foods frequently are not of diagnostic assistance whether done by the scratch, intradermal or passive transfer method. If food sensitivity is considered an etiologic factor the offending food or foods have to be determined by history, observation or the use of an elimination diet. Recovery has been observed in cases in which no change of diet was made.

LEAD POISONING

Lead poisoning sometimes is encountered in pediatric practice. The more common sources of lead are dried paint or putty chewed from walls, window sills or cribs, ingestion of water carried by old pipes, use of storage battery casings as fuel in inadequately ventilated dwellings and contact with lead incident to the casting of lead soldiers or toys. Lead nipple shields are a source of lead to nursing infants. Cerebral symptoms are the most common manifestations of lead poisoning in children though intestinal colic has been observed. A zone of increased density generally can be demonstrated roentgenographically in the epiphyseal end of the diaphysis of the long bones. The knee and wrist are the best regions in which to demonstrate these changes. Basophilic stippling of the erythrocytes is often present. The most specific test is the spectroscopic demonstration of abnormal quantities of lead in the blood or the presence of over 100 micromilligrams of lead per liter in a twenty-four hour specimen of urine.

The pain of the colic may necessitate the use of morphine sulfate hypodermically. The proper dose for an adult is $\frac{1}{6}$ or $\frac{1}{4}$ grain (0.01 or 0.016 gm). The dose for a child may be computed by the formula

weight age
of $\frac{\text{weight}}{150}$ or $\frac{\text{age}}{\text{age} + 12}$. The adult dose previously mentioned is multiplied by the fraction so secured.

Atropine sulfate hypodermically in doses of $\frac{1}{160}$ grain (0.00043 gm) for a fourteen year old child and $\frac{1}{400}$ grain (0.00022 gm) for an eighteen month old infant is often sufficient. Tincture of belladonna administered orally may be useful giving 2 minims to a year old infant and 20 drops to a fourteen year old child.

Inhalations of amyl nitrite may give transient relief from the pain.

ACUTE DIARRHEAS

The diarrheal diseases of infancy and childhood are still encountered though not nearly as frequently as they were twenty-five years ago. Some of these are specific infections due to one of the dysentery or Salmonella organisms. In our practice diarrhea due to nonspecific or parenteral infections is much more frequently encountered. These diseases often are not sufficiently acute to require emergency treatment. However, in two situations prompt medical attention is necessary. The first condition generally is limited to children less than two years of age. This is the washed-out apathetic appearance which occurs suddenly after one or more days of diarrhea and vomiting. It may also appear after the passage of only one or two copious liquid stools. Infants so afflicted should be hospitalized promptly for the administration of intravenous fluids and transfusions. The second situation in which prompt medical attention is indicated is that in which abdominal pain is the initial or the most prominent complaint. This may occur at any age. Careful abdominal palpation will help to decide whether a surgical procedure is indicated. Acute appendicitis has been observed to follow an acute diarrheal episode.

Treatment of the diarrheal diseases may be grouped briefly into three parts: (1) diet regulation, (2) fluid administration and (3) medications.

Restriction of the diet depends on the severity of the disease. In the most severe cases, nothing is given orally for the first twenty-four hours. The time and amount of additions, starting with water, depend on the patient's age and condition. In the less severe infections an initial diet of grated or well-scraped apple and water or apple and boiled skim milk are sufficient restriction. Vitamin supplements given parenterally are often helpful.

The amount of fluid administered depends on the patient's age and the severity of the disease. In the more severe cases parenteral administration is necessary for many days. Continuous intravenous infusion is the most satisfactory method. In small infants scalp veins or small veins of the hand or foot are frequently the best to use. Surgical exposure of the ankle veins is seldom necessary. Infusions of bone marrow using the upper tibia in small infants or the sternum in older children have been extremely useful. Subcutaneous infusion is a useful adjuvant method of administering fluid. The intraperitoneal injection of fluid may be resorted to as an emergency procedure. The following solutions are suggested as being most valuable and readily available commercially if they cannot be prepared locally: isotonic saline (0.9 per cent), 5 per cent glucose in distilled water, 5 per cent glucose in isotonic saline, $\frac{1}{4}$ molar sodium lactate solution and 10 per cent glucose in distilled water.

Ringer's solution and Ringer-lactate solution are valuable but are not always readily available. Sodium bicarbonate in 5 per cent solu-

tion may be employed as an alkalizing agent but it is more difficult to prepare, less stable and more prone to induce alkalosis than is $\frac{1}{6}$ molar sodium lactate solution. The bicarbonate, however, is more prompt in action and is preferable in cases of circulatory failure, hepatic damage and extreme anoxia because the lactate may be oxidized too slowly. Sodium bicarbonate solution is to be given only when the carbon dioxide content of the blood is low and when this estimation may be repeated at regular intervals.

Two to 3 ounces (60 to 90 c.c.) of fluid per pound (0.5 kg.) of body weight is the usual daily requirement of an infant. This must be considered when planning the amount of fluid to be administered to a dehydrated baby. One ounce (30 c.c.) per pound (0.5 kg.) is a minimal amount of fluid to be administered daily to establish hydration in a clinically dehydrated child. As previously suggested, the continuous intravenous route is preferable especially when the patient is moderately or severely dehydrated. If facilities for frequent parenteral administration of fluid exist, "sets" of fluids may be given. These consist of an intravenous infusion and a hypodermoclysis. This method is of particular value when the urinary excretion is low. The hypodermoclysis of isotonic saline, $\frac{1}{6}$ molar sodium lactate solution or Ringer-lactate solution, is started first. Then 10 per cent glucose in distilled water is given intravenously. In the case of an infant who weighs up to 12 to 14 pounds (5.4 to 6.4 kg.), 20 c.c. per pound (0.5 kg.) of body weight is given subcutaneously and 10 c.c. per pound (0.5 kg.) is given intravenously. Concomitantly, continuous infusions both intravenously and subcutaneously may be given. Ten per cent glucose must be given then only intermittently as it has a tendency to cause thrombosis in the vein at the site of the needle. When a continuous intravenous infusion is running, 5 to 8 c.c. per pound (0.5 kg.) per hour may be given when the infant is dehydrated. After that a rate of about 2 to 3 c.c. per pound (0.5 kg.) per hour is advised. The rate of introduction of fluids by the subcutaneous route depends on the patient's ability to absorb the fluid. A two-way hypodermoclysis set in which insertion of a "Y" tube in the tubing allows the fluid to be given simultaneously in two sites is desirable. It is unwise to allow a hypodermoclysis needle to remain in place more than twenty-four hours since it may lead to formation of an abscess.

In some cases of mild or moderately dehydrated infants and children a hypodermoclysis is sufficient to hydrate the patient. Any of the previously mentioned fluids may be given subcutaneously except 10 per cent glucose and 5 per cent sodium bicarbonate.

All of the fluids aid in restoring total fluid balance. The isotonic saline and Ringer's solution aid in restoring the electrolyte volume. The $\frac{1}{6}$ molar sodium lactate and sodium bicarbonate aid directly in combating acidosis. The dextrose solution (5 per cent) and saline solutions aid indirectly in combating acidosis. The dextrose is par-

ticularly useful in correcting the ketosis of starvation. One should be sure, particularly after the patient has been hydrated, that an excess of saline is not given. Edema has been observed under such circumstances.

Citrated whole blood and plasma are useful and often necessary therapeutic additions. They should be given only after the patient first has been hydrated. Infants who weigh up to 10 pounds (4.5 kg) may be given 10 c c per pound (0.5 kg) of body weight. The condition of the patient, the degree of anemia and the degree of hypoproteinemia determine the amounts to be used and whether blood or plasma should be administered. For children from two to four years of age, a pint (500 c c) often is divided into three transfusions to be given on successive days.

The parenteral administration of amino acids has been a definite step forward in parenteral therapy. Hartmann suggested the use of a solution of equal parts of 10 per cent amigen (enzymatic hydrolysate of casein), 10 per cent dextrose and Ringer-lactate solution for subcutaneous or intravenous infusions. Space does not permit further discussion of the use of this material.

In the specific diarrheas sulfaguanidine or sulfasuxidine is given by mouth. The daily dose of these drugs is 2 to 4 grains (0.13 to 0.26 gm) per pound (0.5 kg) of body weight, given in divided doses every four hours. In the nonspecific diarrheas these sulfa drugs also are sometimes useful. A 5 per cent solution of sodium sulfadiazine given subcutaneously may be more valuable. The dose is $\frac{3}{4}$ to 1 grain (0.05 to 0.065 gm) per pound (0.5 kg) of body weight.

Camphorated tincture of opium (paregoric) frequently is employed, probably more often than is necessary. The dose varies from 5 drops for a six months' old infant to 1 teaspoonful (4 c c) for a five year old child. The dose may be repeated every four hours if tolerated. Fresh tincture of iodine (U S P) in 1 to 2 ounces (30 to 60 c c) of water, grapefruit juice or grape juice has been helpful. The dose varies from 2 drops for an infant eighteen months of age to 10 drops for a child fourteen years of age, given three times daily. In cases of mild diarrhea, pectin-kaolin mixtures in teaspoonful doses three or more times daily are valuable.

POISONS

Poisons ingested by children cause damage from either direct action on the gastro-intestinal tract or from the effects produced after the substance has been absorbed.

The most important substances causing damage by direct action are lye, sulfuric acid and lactic acid. If lye is ingested the mouth should be irrigated thoroughly with weak vinegar or lemon juice. The child also should be encouraged to swallow a quantity of this. If an acid solution has been ingested, a 5 per cent solution of sodium bicarbonate should

be used to irrigate the mouth. The patient also should swallow some of this solution. Children who have ingested carbolic acid, lysol (compound solution of cresol) or creosol should have the stomach washed out with large amounts of olive oil or warm water, about 5 ounces (150 c.c.) of olive oil is left in the stomach. If lavaging is not possible, the child should be encouraged to drink 5 to 6 ounces (150 to 180 c.c.) of olive oil. Large amounts of normal saline should be administered by all available routes. The use of dilating instruments should be left to those qualified in their use. Some physicians advise immediate attempts at dilatation and others recommend postponement of this procedure until the initial inflammatory process has completely subsided. At the Clinic we try to have the patient swallow a thread as soon after the burn as possible. Dilatations using the thread as a guide are then not attempted until the acute inflammatory process has subsided.

The other substances which may be swallowed by children are numberless. The introduction of new products for a variety of uses about the home increases each year the number of materials that may be ingested. It is impossible here to do more than suggest a few general principles for use when a situation such as this is encountered. 1. The stomach should be washed out unless the ingested substance is known to be harmless in the quantity ingested. Normal saline or tap water may be used as the irrigating solution. A charcoal suspension may be left in the stomach. 2. When the poison ingested is unknown a universal antidote composed of pulverized charcoal (2 parts), magnesium oxide (1 part) and tannic acid (1 part) may be given. The dose is 4 c.c. (1 teaspoonful) in a small glass of warm water. 3. If metals such as arsenic, lead or mercury are ingested, an irrigating solution of sodium thiosulfate, 15 gm. in 2 liters of water, should be used. If phosphorus has been ingested, oil should not be given as this increases the speed of absorption. The best antidote is a weak solution of copper sulfate. 4. If convulsions are present, lavage should be avoided. 5. Shock, convulsions, respiratory or circulatory failure, pain and other symptoms must be treated as they develop. Sedatives or stimulants may have to be given rectally, intravenously or intramuscularly. An anesthetic agent may be required to control severe convulsions.

NONSURGICAL NEUROLOGIC EMERGENCIES IN CHILDREN

HADDOW M KEITH

SINCE the nervous system frequently is intimately concerned in severe and acute disease, so-called neurologic emergencies are numerous and of great variety. This paper is an attempt to present a number of the more common conditions involving mainly the nervous system of the child and requiring early diagnosis and immediate treatment. All these conditions will not be discussed exhaustively and consequently information concerning the technic of surgical treatment must be sought elsewhere. Some conditions will be discussed in different categories since at times it is necessary to deal with symptoms rather than recognized disease processes. The most common neurologic emergencies have been divided into five groups and will be discussed in the approximate order of frequency as follows: (1) convulsion, (2) head injury, (3) coma, (4) infection and (5) poisoning.

CONVULSION

Etiology—The causes of convulsion are many. Most of them are included in the following list:

Acute infectious disease	Intracranial abscess
Brain tumor	Intracranial hemorrhage
Congenital cerebral defect	Meningitis
Congenital syphilis	Strychnine poisoning
Direct trauma	Tetanus
Epilepsy	Tetany
Gastro-enteritis	Uremia
Hydrocephalus	

General Emergency Treatment—In spite of the fact that one or more of the foregoing causes may be present and the fact that a correct diagnosis is essential before effective treatment can be instituted, convulsion frequently must be treated as an emergency. It is usually difficult to stop an individual convulsion but a series of convulsions may be treated effectively by medical or physical agents. As a rule, a general anesthetic agent produces the best results, and since ether is usually readily available and its action is well known, this is the agent of choice. The barbiturates, which may be given intravenously, subcutaneously or rectally, are also satisfactory.

Pentothal sodium [sodium 5-ethyl-5-(1-methyl-butyl) thiobarbiturate] is used intravenously for immediate effect. As a rule, this drug is not given to children less than ten years of age in connection with operations, however, in an emergency it may be given to young children in small doses, beginning with 1 c c of a 2.5 per cent solu-

tion and giving 0.5 to 1 c.c. at intervals of ten to fifteen seconds until the convulsion is controlled. At the same time the rectal administration of pentobarbital sodium, $\frac{1}{2}$ to 3 grains (0.032 to 0.2 gm.), is begun. This medication should be repeated at intervals frequent enough to prevent further attacks until the underlying causative condition has been corrected and there is no likelihood of further attacks.

Sodium amytal (sodium isoamylethylbarbiturate) has been used intravenously in a 5 per cent solution (5 mg. per kilogram of body weight) at a rate not exceeding 1 c.c. per minute. Its action is somewhat slower than that of pentothal sodium and its effect is more prolonged.

The rectal administration of avertin fluid (tribromoethanol) in the usual basic anesthetic dose of 75 mg. per kilogram of body weight, also has been effective in controlling a series of convulsions. This is supplied in amylene hydrate so that 1 c.c. contains 1 gm. of avertin and 0.5 gm. of amylene hydrate.

Another effective agent for rectal administration is chloral hydrate. This may be given every two to four hours in doses of 3 to 15 grains (0.2 to 1 gm.) depending on the age of the patient.

At times magnesium sulfate has been effective, especially in the control of convulsions caused by acute nephritis. This medication is administered intramuscularly in a 10 or 25 per cent solution (0.2 gm. per kilogram of body weight) and is repeated every four to six hours if necessary.

Oxygen given by means of a tent or mask is sometimes effective in controlling a series of convulsions, particularly if cyanosis is present. It may be used in conjunction with any of the previously described medications.

In certain cases, lumbar puncture with drainage of a few cubic centimeters of spinal fluid may also be beneficial but there is some danger in this procedure if there is increased intracranial pressure.

In certain conditions some measures are more efficacious than others and in some conditions specific measures are necessary. The most important points in treatment are discussed under the various causes of convulsion.

Acute Infectious Disease—Convulsions commonly occur at the onset of an infectious disease among young children. Since such an attack may be dependent on high fever, measures to reduce the temperature, followed by specific treatment if possible, should be undertaken. The administration of an enema using cold tap water or even ice water is of considerable help. After this the body may be sponged with tepid water, or a tepid pack may be applied. These measures may be followed by the administration of acetylsalicylic acid. The administration of anticonvulsant drugs usually is unnecessary unless a series of convulsions occurs.

Brain Tumor—Relief of pressure by operation is imperative when

brain tumor is present Tumor of the brain is a relatively uncommon cause of convulsion but the pediatrician should keep in mind the cardinal symptoms and signs, that is, headache, vomiting, ataxia, swelling of the optic disks and roentgenologic evidence of increased intracranial pressure such as separation of sutures and digitations in the skull

Congenital Cerebral Defect—General anticonvulsant measures are useful No treatment of the underlying cause is possible

Congenital Syphilis—General measures, as previously outlined, followed by antiluetic treatment, should be instituted for convulsions caused by congenital syphilis This condition is rarely encountered at the Clinic

Direct Trauma.—In cases of concussion only, with no evidence of fracture, hemorrhage or laceration, general measures for control of convulsion may be used Direct trauma is essentially a surgical condition

Epilepsy—The single convulsion of grand mal, which is relatively short in duration, usually cannot be stopped once it has started When status epilepticus occurs, most of the general procedures for treatment of convulsions are effective, either alone or in combination

Gastro-enteritis—The fever or toxicity that is associated with gastro-enteritis probably is the precipitating factor in convulsion Treatment is the same as for convulsion caused by acute infectious disease Since dehydration is usually present, adequate amounts of fluid should be supplied

Hydrocephalus—The diagnosis is dependent on abnormal enlargement of the head, with demonstration of an excessive amount of cerebrospinal fluid and enlargement of the ventricles In external hydrocephalus the enlargement is due to fluid outside the ventricles Convulsions caused by either internal or external hydrocephalus should be treated by general measures, followed by surgical treatment of the underlying condition if possible

Intracranial Abscess—Diagnosis of intracranial abscess is usually difficult The presence of such a condition is suggested by evidence of infection and of focal involvement of the nervous system Treatment consists of general measures to control the seizures, followed by surgical treatment of the abscess

Intracranial Hemorrhage—Convulsion, either focal or general in type, may be the result of hemorrhage due to injury at birth or to any gross injury of the head If the bleeding is due to birth injury, chloral hydrate in doses of 1 to 3 grains (0.065 to 0.2 gm) by mouth or by rectum or pentobarbital sodium, $\frac{1}{4}$ to $\frac{1}{2}$ grain (0.016 to 0.032 gm), by rectum may be tried Magnesium sulfate administered intramuscularly also has been satisfactory

If the fontanelle is tense, spinal drainage may be indicated Objections to this procedure have been raised on the basis of the fact that it dis-

turbs the patient and the lowering of the intracranial pressure may increase the tendency to hemorrhage. The administration of oxygen by use of a tent frequently is indicated. Menadione, 1 mg daily for seven to ten days, should be given intramuscularly.

If the hemorrhage is due to direct trauma, particularly if the middle meningeal artery is ruptured, surgical treatment is indicated.

Meningitis—Convulsion due to meningitis requires immediate treatment by general measures, followed by active treatment of the meningitis. This subject is discussed in the section concerning coma.

Strychnine Poisoning—Because of the prevalence in homes of preparations containing strychnine, convulsions due to this drug are not an uncommon occurrence. In spite of all precautions, children obtain and take these remedies and generalized seizures rapidly develop. The diagnosis usually is suggested by the history of swallowing excessive amounts of either a tonic or pills and the subsequent occurrence of generalized tonic convulsive seizures. The following immediate treatment, in the order given, has been effective: (1) pentothal sodium administered intravenously, as previously described, (2) insertion of a tracheal catheter to overcome the laryngeal spasm, followed by the administration of oxygen by use of a mask or tent and (3) pentobarbital sodium, $1\frac{1}{2}$ to 3 grains (0.1 to 0.2 gm), given by rectum. This amount should be repeated frequently enough to prevent further convulsions for twelve to twenty-four hours or until danger of further convulsions is over.

Convulsions as well as other neurologic emergencies in children, may be due to many different poisons. Because of the extensiveness of the subject of poisoning it will not be discussed further in this paper and the reader is referred to other works for further information.

Tetanus—In our experience at the Clinic, convulsion due to tetanus has been infrequent in occurrence. The use of prophylactic antitoxin in cases of contaminated wounds undoubtedly has been a major factor in reducing the incidence to a minimum. In addition, active immunity may be produced by the use of tetanus toxoid, this method has been reported as satisfactory in Army practice. However, when convulsions occur suddenly and without obvious cause, the possibility of tetanus must be considered, and a search for a focus of infection, however small, should be made.

The paroxysms may be initiated by any stimulus, however slight. Such stimuli include sounds, sights, attempts at voluntary movement, and even light touch or pressure at any point.

The character of the convulsion caused by tetanus is rather distinct. There is preceding stiffness of the neck and jaw, with difficulty in swallowing. The convulsive attack is really a spasm in which the patient is in the opisthotonoid position with the body completely rigid and the head retracted. The face has a fixed expression, with firm contraction of the muscles of the jaw. There may be a single attack last-

ing only a few seconds, or attacks may occur constantly so that the patient is in almost continuous convulsions. The respiratory mechanism may become involved so that breathing is impossible.

In treating such a patient, all stimuli must be reduced to a minimum. The child must be kept in bed in a darkened room and handled as little as possible. Feeding may be carried out by means of a nasal tube, and glucose and saline may be given intravenously by continuous drip.

Avertin with amylene hydrate has been found effective in controlling convulsions caused by tetanus. The usual anesthetic dose (75 mg per kilogram of body weight) may be given rectally, followed at intervals of one to three hours by further administration of 10 to 15 mg per kilogram of body weight.

Sodium amytal may be given intravenously, and pentobarbital sodium also may be used. Use of these drugs is described under general emergency treatment.

Curare (intocostin)* also has been used intramuscularly and intravenously. Cullen and Quinn⁵ gave approximately 0.05 gm every three hours to an adult male. This dose is approximately 0.0008 per kilogram of body weight. It should be used in sufficient amount and often enough to relieve the pain and muscular spasm.

A large amount of antitoxin should be given as early as possible after the occurrence of convulsion due to tetanus. Calvin² advised the intravenous injection of 50,000 units of antitoxin as follows: Test patient for sensitivity to horse serum, then dilute the serum in 500 c c of physiologic saline at body temperature and give intravenously at the rate of 60 drops per minute. If chill occurs, stop the intravenous injection and give the remainder of the serum intramuscularly. In addition, give another 50,000 units intramuscularly. Holt and McIntosh⁸ advised that the primary wound be excised and antitoxin given no matter how much antitoxin previously had been administered.

To, any—Convulsion in infants and small children who are less than three years of age is sometimes caused by tetany, usually associated with some degree of rickets. Such a seizure is particularly dependent on a low level of calcium, many patients having less than 8 mg per 100 c c of serum. Chvostek's sign is present. This consists of increased irritability of the peripheral nerves as noted by clonic contractions of the facial muscles of one side when the seventh nerve is lightly tapped. Further evidence of the presence of tetany is obtained by Trousseau's sign, that is, the tetanoid position of the hand when firm circular pressure is made about the upper arm.

Convulsions due to tetany may be generalized and may be indistinguishable from convulsions due to other causes. They may be controlled by one of the following methods. Calcium gluconate in 10 per cent solution may be given intravenously or intramuscularly, in 10 c c doses every four to six hours. Sloughing occasionally may oc-

* Prepared by E. R. Squibb & Sons, New York City

cur after intramuscular injection. Calcium chloride may be given by mouth or in extreme cases by vein. The latter method must be used with care since injection of the solution outside a vein may cause sloughing. When calcium chloride is given orally the initial dose is 45 to 60 grains (3 to 4 gm) in 10 per cent solution in water or milk. This is followed by a dose of 15 grains (1 gm) three or four times daily. Twenty-four hours after calcium therapy has been started cod liver oil or other vitamin D preparation should be given and continued indefinitely. Chloral hydrate may be given orally or rectally. Three to 5 grains (0.2 to 0.3 gm) may be given to infants less than six months of age and 5 to 10 grains (0.3 to 0.65 gm) to children more than six months of age. In some cases of convulsion, the administration of ether may be required.

Uremia—Uremia, or pseudo-uremia in the course of nephritis may precipitate convulsion. When the blood pressure is elevated, uremia may develop regardless of whether the retention of nitrogen is excessive. Under such circumstances drowsiness or vomiting with the onset of coma, may be accompanied by generalized convulsive attacks.

Uremic convulsions may be treated by any of the methods previously outlined under emergency treatment. Lumbar puncture is one of the methods of choice. Some authors recommend, in addition the use of morphine. Magnesium sulfate in 2 per cent solution should be injected intravenously not faster than 2 c.c. a minute, until the blood pressure returns to normal. After the convulsions have ceased and the patient is no longer in a state of coma, large doses of a saturated solution of magnesium sulfate should be given by mouth until the blood pressure is stabilized. The patient should be urged to take fluids in large amounts.

HEAD INJURY

Children frequently receive injuries to the head. Most of these cases must be considered as of an emergency nature. The lesions may be the result of birth trauma with or without hemorrhage or of trauma from external causes with or without hemorrhage. The injury may or may not be associated with fracture or loss of consciousness. In many cases surgical treatment, which is beyond the scope of this discussion, is necessary.

Head Injury without Loss of Consciousness—The parents should be informed that the child may become pale, may vomit once or several times and may be unusually quiet for several hours. Although these symptoms are not of grave import, if increasing drowsiness is noted, immediate medical or surgical attention is necessary. Hematomas and lacerations necessitate surgical treatment. The patient should be at rest in bed until a day or two after these symptoms have disappeared.

Head Injury with Concussion—The patient must be kept absolutely at rest in bed in the horizontal position for from several days to sev-

eral weeks, depending on the signs and symptoms. Frequent observations of the pulse rate, temperature, respirations and blood pressure are of great importance. Shock must be treated immediately with transfusion of blood, plasma or serum albumin or infusion of glucose and saline. Scalp wounds, hemorrhage and fractures of the skull require surgical consideration and treatment. A gradual rise in intracranial pressure over a period of some hours also indicates the necessity for surgical consultation. If unconsciousness persists, feeding by tube may be necessary.

Head Injury with Hemorrhage—Surgical treatment, in addition to general measures, usually is indicated in cases of head injury with hemorrhage. Lumbar puncture is contraindicated since it may increase the bleeding. Craig⁴ recently stated that in both open and closed injuries anoxia should be prevented by insuring free passage of air for adequate breathing and by administering oxygen. He also pointed out that the sulfonamides and penicillin "have so reduced the incidence of infection that the scope of surgical treatment has been immeasurably increased."

Hemorrhage due to rupture of the middle meningeal artery with the formation of subdural hematoma always requires emergency treatment. There is a history of trauma with or without loss of consciousness. If the patient is unconscious, he subsequently may become conscious for a half to one hour and then gradually become increasingly drowsy with headache or vomiting and slowing of the pulse rate. In addition, there are focal neurologic signs, such as a dilated pupil on the side of the hematoma and positive Babinski and Chaddock reflexes on the opposite side. Roentgenograms reveal fracture of the skull. As soon as the diagnosis is made, treatment is entirely surgical.

COMA

Coma, which is only a sign of an underlying disease or injury, is often encountered, particularly in hospital practice. Determination of the etiology is of prime importance, since treatment depends almost entirely on the cause. The many common causes of coma include head injury, brain tumor, meningitis, pyogenic and tuberculous infection, acute encephalitis, diabetes, uremia, acute infectious diseases, poisons, intracranial hemorrhage and status epilepticus. Several of these conditions are discussed elsewhere in this paper. Some of the rarer causes of coma are narcolepsy, cerebral embolism, thrombosis and hepatic insufficiency.

Brain Tumor—In many cases of tumor of the brain there is a history of weeks or months of vomiting and headache frequently associated with muscular weakness, ataxia and perhaps increasing drowsiness or lassitude. Examination usually reveals evidences of increased intracranial pressure, such as papilledema, and roentgenographic evidence of separation of the cranial sutures. Detailed neurologic examination

may reveal focal signs which give a clew to the site of the tumor. Surgical treatment usually is indicated. If this is not feasible, roentgen treatment may give palliative relief.

Diabetes—Coma caused by diabetes mellitus is primarily a metabolic and not a neurologic problem. A history of diabetes mellitus may or may not be obtained. Glycosuria, acetonuria and hyperglycemia usually are demonstrable, as well as a low content of carbon dioxide in the plasma. In cases of coma due to an overdose of insulin these findings are not present and the history of administration of insulin plus hypoglycemia gives the clew to diagnosis. Treatment of diabetic coma requires skill, close observation and laboratory facilities such as are found in a well-equipped hospital and preferably should be undertaken only when these conditions are fulfilled.

Encephalitis (Acute)—This subject is discussed subsequently under the heading of infection.

Head Injury—The diagnosis of coma due to an injury to the head usually is indicated by the history of trauma or by the obvious evidences of direct injury. In occasional cases no history is available. A careful examination of the head, including roentgenograms, may indicate the site of the trauma. Treatment of such a condition is outlined in a preceding section concerning convulsion due to direct trauma.

Meningitis (Pyogenic and Tuberculous)—In cases of pyogenic meningitis, evidence of acute infection, such as fever possibly with headache, convulsion and elevation of the leukocyte count, is present. These symptoms and signs are accompanied by nuchal rigidity and, as a rule, Kernig's sign. The patient may lie with the head retracted and may have considerable general rigidity of the muscles. The spinal fluid usually is under increased pressure and contains large numbers of leukocytes and an abnormal amount of protein. On direct examination of the fluid, organisms may be present, or may be cultured on the usual media. Treatment is outlined under a subsequent section concerning infection.

In cases of tuberculous meningitis, the onset is usually more gradual than in cases of pyogenic meningitis, with change in personality, increased irritability, fretfulness, headache in older children, anorexia and sometimes unexplained vomiting. The acute onset of symptoms such as convulsion or coma, which occur in infants requires emergency treatment. The pressure of the spinal fluid may be considerably increased. It is clear or faintly cloudy and contains mainly lymphocytes, from 25 cells to several hundred cells per cubic millimeter. Occasionally neutrophils predominate. The content of protein is moderately elevated, and the amount of chlorides and sugar is reduced. Tubercle bacilli usually may be found in the fluid, especially in the fibrous pellicle which often forms on allowing the fluid to stand for some hours. Organisms also may be demonstrated by staining a cover-

slip which has been placed for twelve hours or so in the bottom of a glass cell containing spinal fluid

There is no satisfactory treatment for tuberculous meningitis. Convulsions should be treated as outlined under emergency treatment. The newer drugs, such as promizole (4, 2'-diaminophenyl-5' thiazole-sulfone), have given some therapeutic promise but they are still in the experimental stage.

Uremia—This condition, which also is primarily a metabolic disturbance, is discussed in detail in another paper⁹ in this issue.

Unusual Conditions—Among the rarer causes of coma and similar states in children may be mentioned narcolepsy, cerebral thrombosis or embolism, and hepatic insufficiency.

Narcolepsy may not be considered as true coma but older children occasionally may be found in an unconscious state during an attack. No immediate treatment is required but benzedrine sulfate (amphetamine sulfate) or ephedrine have been found of considerable value in preventing the recurrence of attacks of somnolence.

Cerebral thrombosis or embolism is rare in childhood. The former may occur in the larger veins or sinuses in cases of acute infectious disease or of sepsis and dehydration in infants. The most common is thrombosis of a lateral sinus, associated with otitis and mastoiditis. This is essentially an otologic condition and the treatment is surgical. Cavernous sinus thrombosis is discussed in the following section concerning infection.

Coma, maniacal states and even convulsions may occur in *hepatic insufficiency*. A trial of treatment with glucose in 10 per cent solution, with or without insulin, may tide the patient over such a difficulty.

INFECTION

Cavernous Sinus Thrombosis—This severe and often fatal condition may occur as an emergency. It usually takes the form of thrombophlebitis, which at first may be unilateral but later may become bilateral. There is usually a source of infection about the upper portion of the face or in the nose, and infection of the blood stream is frequently present, the organism being staphylococcus or streptococcus. The patient complains of headache or pain in the forehead, about or behind the eye. There also may be pain in the teeth on one side. The general reaction is severe enough at times to cause delirium.

The physical signs consist of edema of the eyelids, exophthalmos or severe proptosis, ptosis, chemosis and weakness of the various extraocular muscles. Papilledema and engorgement of the retinal veins also may be present. The spinal fluid may be cloudy and contain many leukocytes.

Prior to the advent of treatment with the sulfonamide compounds and penicillin, management was ineffective. Recently recoveries have

occurred following the use of these preparations, with or without heparin.

Cohen and Cohen,⁸ in 1942, reported the successful treatment of a two year old child following the administration of sulfathiazole orally and intravenously, heparin and *Staphylococcus aureus* antitoxin. Edelson,⁹ in 1944, reported the recovery of one patient after the use of sulfathiazole, sulfadiazine and heparin. Goodhill⁷ reported one case and Wiesenfeld and Phillips¹⁰ also reported a case in which favorable results followed treatment with penicillin and heparin or with penicillin alone. In both cases large doses of penicillin were administered, a total of approximately 1,000,000 Oxford units being given to a five year old child, and 2,000,000 to a young adult. The larger part of the penicillin was given intravenously in amounts of 50,000 to 150,000 units daily.

Encephalitis (Acute).—The occurrence of convulsions or coma as a result of acute encephalitis may require emergency treatment. There are many varieties of encephalitis, the most definite types being epidemic encephalitis, acute polioencephalitis, encephalitis following vaccination, encephalitis complicating acute infectious diseases and encephalitis due to poisons such as lead or arsenic. A rather rare form, toxoplasmosis, may occur in early infancy and may be of congenital origin.

Such patients usually have high fever, delirium, convulsions or coma and there may be signs of meningeal irritation. Ataxia may be pronounced, asphyxia may develop or signs of lesions of one or more of the cranial nerves may be present. The prognosis is poor except in the postinfectious types of encephalitis. If the patient survives, there are frequently residual symptoms such as mental disturbances, paresis or paralysis.

Treatment is not of a specific type but is essentially symptomatic. Lumbar puncture and the use of anticonvulsants or sedatives are indicated, as discussed earlier in this paper in the section concerning convulsions. Hot packs or baths also may be employed. Food and fluids may be given by gavage, and fluids alone by parenteral injection. If retention of urine occurs, catheterization is necessary.

Intracranial Abscess.—An intracranial abscess may require emergency treatment due to extension from acute mastoiditis or sinusitis. Such a patient may have alarming symptoms such as aphasia, hemiplegia, delirium or coma. There is usually a history of infection of the middle ear, mastoid or sinuses with elevated temperature, increased leukocyte count, physical signs of meningitis and evidence of acute meningitis on examination of the spinal fluid.

Treatment, which is essentially surgical, consists of evacuation or aspiration of the abscess. Sulfonamide compounds or penicillin or both also should be administered.

Meningitis (Acute).—This condition at times requires emergency

treatment because of its sudden onset, with or without convulsion or coma. The important diagnostic criteria are outlined in a preceding section. Treatment consists of control of convulsions, if present, and of the meningitis. Treatment depends to some extent on the type of infecting organism, but at the present time it consists primarily of use of one of the sulfonamide compounds or penicillin or both. Sulfadiazine usually is the sulfonamide compound of choice at the present time. It can be given intravenously, subcutaneously or orally in such amount that the level of the drug in the blood is above 15 mg per 100 c.c. It is advisable also to give enough sodium bicarbonate to keep the urine alkaline. The penicillin may be given intravenously by continuous drip, intrathecally or intramuscularly, giving 80,000 Oxford units daily, 10,000 units every three hours.

Anti-influenzal rabbit serum has been advised in cases of influenzal meningitis in addition to the use of sulfadiazine. Alexander¹ recommended that it be given about twelve hours after beginning sulfadiazine in amounts of 100 to 150 mg of antibody nitrogen if the sugar in the spinal fluid is less than 15 mg per 100 c.c. If the spinal fluid sugar is between 12 and 25 mg, 75 mg of antibody nitrogen should be given, if it is between 25 and 40, 50 mg, and if more than 40, 25 mg.

Tuberculous meningitis, which requires emergency treatment only if convulsions or sudden coma develop, is discussed in a preceding section concerning coma.

Tetanus—Information concerning this subject is given under convulsion.

CLINICS ON OTHER SUBJECTS

POSTWAR ASPECTS OF SOME TROPICAL DISEASES

GEORGE G. STILWELL

At the present time there is considerable discussion throughout the United States concerning the possibility of a great postwar increase in the incidence of tropical diseases both in the returning armed forces and in the civilian population. There is also speculation about whether new diseases not heretofore present in this country will be imported, and in such event, if the proper vectors are present, whether such new diseases will establish footholds and spread throughout areas which are suitable for the propagation of these diseases.

No doubt the practicing physician will see many more cases of so called tropical diseases in the next decade or two than he has encountered in his past experience, and his diagnostic acumen often will be taxed by the bizarre clinical pictures which some of these unfamiliar disease entities will present. In recognition of this probability, there has been considerable acceleration during the last two years in the teaching program of tropical medicine from the standpoint of both the clinician and the laboratory diagnostician. This is evident in the greatly expanded departments of tropical medicine in both the Army and the Navy Medical Corps. The medical schools of North America also have felt the effect of this increased emphasis on thorough training in tropical diseases, and a plan for improvement of the teaching of tropical medicine in the medical schools of the United States and Canada has been developed through co-operation of the Association of American Medical Colleges, the Office of the Surgeon General of the United States Army, the National Research Council, the Army Medical School and Tulane University. This plan is being aided financially by the John and Mary R. Markle Foundation.

Various aspects of this problem have been studied by specialized workers in tropical diseases and by leaders in the field of public health. The conclusion drawn from these studies is that the return to this country of many diseased members of the armed forces presents definite potential dangers to the health of the nation. It is also the consensus that the importance of these potential dangers perhaps has been overemphasized in the mind of the average physician. It is evident that the Army, the Navy, and the public health authorities are fully aware of all the possibilities inherent in the forthcoming situation, and that these agents together with a medical profession better trained in tropical medicine, will be able to cope with any developments which might ensue.

The importance of this problem as related to the general population of our country warrants a brief discussion of some of the more

important of these potentially dangerous diseases Particular emphasis should be placed on an attempt to anticipate what may be the future course in the United States of the diseases which are imported by our returned fighting men It is plainly evident that our soldiers and sailors are being exposed to more diseases in the present global conflict than they have been at any other time in history, and it is a foregone conclusion that they will bring some of these diseases home with them

Several important factors concerned in the method of spread of these diseases should be considered before the individual disease entities are discussed The acute diseases, which have a comparatively short period of incubation and communicability, are less likely to be introduced to this country than those diseases that are of a chronic nature or that possess a long incubation period Those diseases which require for their propagation a specific intermediate host may be imported into this country but they cannot become established as endemic foci unless there is already present this specific intermediate host It is possible that in these cases the specific host also may be introduced and may thrive in some sections of the United States There may be a greatly increased number of asymptomatic carriers of certain diseases returning to this country when demobilization occurs It is possible that new and much more pathogenic strains of organisms may be imported which will produce disease of heightened severity in the civilian population Finally, some diseases which are at present localized in comparatively small areas in this country may be much more widely distributed by the return of men from these endemic areas to their homes

ACUTE DISEASES

The group of acute diseases by virtue of their short incubation period probably will not present any particularly grave postwar menace to civilian health

The first of such acute diseases is *yellow fever*, whose etiologic agent is a virus Yellow fever may be considered to be a historical curiosity here in the United States because it was last seen in 1905 in New Orleans Without eternal vigilance, however, another introduction of this disease is possible As far as geographic distances are concerned, we are farther away from yellow fever than ever before because it is now absent from Mexico, the West Indies, and the upper part of Central America If we use air travel time as a measure of distance, however, we are much nearer yellow fever than ever before because this infection is still found in Colombia, Venezuela, and some parts of Panama.

There appears to be little chance that members of the armed forces will introduce the virus to this country by returning from areas where yellow fever is endemic, while the disease is still in the incubation

period. This is because of the practice of universal vaccination against yellow fever of all personnel entering areas where the disease is endemic. By use of the mouse protection test, it has been found that yellow fever exists in new and vast areas where previously it has escaped detection. These areas are in Africa, where the endemic zone extends eastward more than 3,000 miles to the upper Nile, and in Brazil along the Amazon basin, together with important areas of Colombia and Venezuela. The discovery of yellow fever in the jungles of South America has emphasized the importance of vaccination as a means of prevention because the ordinarily effective measures of mosquito control that have been so successful against the vector of urban yellow fever; namely, the domestic *Aedes aegypti*, are powerless against yellow fever which occurs in the great expanses of almost uninhabited tropical forest.

In such areas vaccination is the best means available for protection against the disease. The vaccine in present use is a strain of living yellow fever virus which has been modified by prolonged passage through tissue cultures until it has lost much of its neurotropic and viscerotropic virulence. It still, however, retains considerable antigenic effectiveness. Many studies indicate that the immunity produced in most vaccinated individuals persists for at least four years. Effective protection may last even longer than this in view of the lifelong immunity conveyed by the disease itself.

The vaccine in its present state is as safe as any biologic agent containing virus can be. Before the present form of vaccine was available, small amounts of human serum were used in the manufacture to aid in preserving the virus. A form of hepatitis resembling catarrhal jaundice developed in many persons injected with the vaccine containing this human serum. After exhaustive study it was concluded that this hepatitis probably was due to some icterogenic agent, perhaps a virus, encountered occasionally in human serum and inadvertently introduced into the vaccine during its manufacture. In the newest type of vaccine, chick embryo juice is substituted for the human serum. During the last two years millions of injections of this serum-free vaccine have been administered and there have been no further reports of jaundice or other symptoms except slight fever and occasional malaise occurring about a week after injection.

The greatest danger of a possible postwar introduction of yellow fever is through the medium of air travel. Several measures are being used to control this danger and vigilance must be maintained if we are to avoid this menace. All persons traveling into endemic areas are urged to be vaccinated against yellow fever. Persons returning from endemic regions are given regular inspections by quarantine authorities. Their temperature is recorded. Anyone who shows signs of illness or an elevated temperature is detained pending a definite diagnosis. If a person is well but has not been vaccinated against vel-

low fever and possibly has been exposed to the disease, he is kept under observation at his destination by health officials until the six day incubation period is past. These latter precautions are not necessary if the destination is north of any areas where *Aedes aegypti* is found. Airplanes returning from areas where yellow fever occurs are thoroughly sprayed to kill all incoming insects.

The impression should not be gained that vaccination is a preventive agent which makes further mosquito control unnecessary. Extirpation of *Aedes aegypti* is still the best method for control of yellow fever in cities and other accessible places in the tropics and subtropics. Because *Aedes aegypti* is primarily domestic in its habits it is quite accessible and therefore is particularly vulnerable to anti-mosquito measures. The efficacy of these measures has been proved in Brazil where in most cities and in many comparatively extensive areas *Aedes aegypti* can no longer be found.

Sawyer² has stated that there are three lines of defense against post-war introduction of yellow fever. The first line is vaccination and the elimination of the mosquito vector from seaports in endemic areas. The second line of defense may be regarded as the various quarantine procedures at our borders. The third line of defense is the eradication of *Aedes aegypti* wherever it exists in the United States. If these measures are taken, they are adequate to keep our communities non-infectable by yellow fever without resorting to general vaccination of the civilian population.

Dengue fever has the same mosquito vector, *Aedes aegypti*, as does yellow fever, and thus the problems of mosquito control are common to these two diseases. Dengue fever is already endemic in the American tropical and subtropical regions. It is important from a military standpoint as it may cause epidemics in the armed forces rendering troops temporarily unfit for active fighting. Because it has a short incubation period, the only danger of an extensive new introduction of it into the United States lies in the possible importation of the disease from Latin America. Until *Aedes aegypti* is eradicated from our southern states the danger of future epidemics remains a definite threat.

Among rickettsial diseases, one is to be feared above all during times when great masses of troops are engaged in conflict. That one is *louse-borne typhus fever*. We need not consider here the comparatively innocuous murine or flea-borne typhus fever, which has been endemic for years in the southern areas of the United States.

Louse-borne typhus is most prevalent in late winter and spring, and thus the cold weather present in the United States would not be a deterrent to its spread. The body louse is the vector concerned in this form of typhus. At the present time, except for slum areas, this insect is comparatively scarce in this country. Therefore, we should feel fairly secure against any extensive invasion of this type of typhus.

fever This security is further bolstered by the fact that modern de-lousing procedures in returning troops are much more efficient than in World War I

The tremendous efficacy of the newest insecticide, commonly known as DDT (1,1,1 trichlor-,2,2 diparachlorophenyl-ethane), is proving a vital factor in the present low rate of typhus, both in the armed forces and in the civilian populations with which they are mingling Thus it appears improbable that there is much danger of wholesale introduction of typhus fever into this country by our armed forces.

Another factor which will be of great importance in preventing postwar spread of this disease is the universal vaccination against typhus which is being performed on all military personnel who go to areas where they may possibly be exposed to typhus fever The efficacy of the type of typhus vaccine being used at present is evident in the practically complete absence of typhus fever in our troops in North Africa and Italy This freedom from typhus is even more remarkable when we consider that extensive epidemics of abnormally severe typhus have occurred in the natives of the African area within the last two years, and that many cases of typhus have developed in unvaccinated British troops living in the same localities as our vaccinated troops

The future situation in this country with respect to the danger of introduction of typhus to the civilian population appears quite safe if the occurrence of the body louse is kept controlled

Several other acute diseases may be briefly considered *Plague* should not be any more of a problem after the war than it is at present in the western states A vaccine is available for use in our troops abroad and it appears to be moderately effective There should be no new outbreak of plague unless there is some breakdown of our present efficient system of ship inspection which might allow new introduction of infected rats

Phlebotomus fever, or sandfly fever, is another disease which has occurred in a large number of troops It is of short duration, usually three or four days, but it is of military importance because the afflicted person is quite disabled for military action during its course It should not create any postwar problems because the *Phlebotomus* fly is found here in only a few small regions

Cholera has not been encountered to any great extent in the fighting men However in the event of a more extensive Burman and Indian campaign causing widespread native epidemics, the disease may appear in our men stationed in these areas A fairly efficient vaccine is available for prophylactic use in persons who are to enter zones where cholera is endemic The likelihood is extremely remote that any person could become a carrier of the *Vibrio* and bring it back to this country Thus we should not have any problems with this disease after peace comes

CHRONIC DISEASES

Among the chronic diseases which might create postwar problems, first and foremost from the standpoint of military importance is *malaria*. The scope of this discussion does not permit full consideration of the diffuse manifestations of this problem, but a few of the more important aspects will be outlined.

It is obvious that large numbers of our troops are being infected with malaria, particularly those fighting in the South Pacific area and in Italy. In spite of proper treatment many relapses have occurred, and the disease may remain latent for many months. Suppressive treatment with atabrine tends to prevent the initial clinical appearance of malaria for periods as long as a year after infection. Thus it appears impossible to prevent the return to this country of large numbers of men infected with malaria.

The chief problems arising from the return of these malarious individuals from abroad may be summarized, according to McCoy,¹ as follows: 1. There is a possibility of establishing new endemic foci of disease in regions which are now free from malaria. 2. Importation of new strains of the parasite may occur in areas where the disease is already prevalent, with a resulting increase in the amount of malaria in these areas. 3. There must be prompt recognition and proper treatment of relapses occurring in soldiers returned to this country.

Much attention has been directed to the first of these problems, namely, the establishment of new endemic foci. Every section of the United States contains anopheline vectors capable of transmitting malaria. *Anopheles quadrimaculatus* is fairly numerous during the warm seasons in many areas which at present do not have malaria. This is especially true in such regions as the Upper Mississippi basin and the Hudson Valley.

One suggestion which has been made is to segregate for a certain period of time all personnel returning from malarious areas, especially if these men are to be sent to parts of the country where malaria is not present. This procedure is obviously impractical because relapses may occur after many months, during which time there has been no clinical or laboratory evidence of infection.

The past history of previous outbreaks of malaria in nonendemic areas of the United States would indicate that the potential dangers in allowing dispersion of these infected individuals are not particularly great. These outbreaks of malaria have consisted of only a few cases and have been characterized by a tendency to remain confined to small areas and a propensity for spontaneous subsidence even without added measures of mosquito control.

The second problem is the possibility of importation of new strains of malarial parasites. Clinical experience with infected troops in the South Pacific tends to indicate that the strains of malarial organisms being encountered there are quite different from those already en-

demic in the United States. These conclusions are drawn from the fact that the relapse rate is much higher in individuals acquiring malaria in the Pacific islands than it is in persons infected in the United States. This greatly increased relapse rate has occurred in spite of intensive treatment. Another bit of clinical evidence to strengthen this conclusion is the high rate of infection among American Negro troops. These colored troops have had the same rate of malarial infection as have the white troops living under the same combat conditions. This is in contrast to the condition existing in the southern part of the United States where Negroes appear to have considerable immunity to the malarial parasites found in this country.

There is a definite possibility that these more virulent strains will be imported into communities where the inhabitants have little or no natural immunity to these new parasites. However, the danger of this introduction resulting in any serious epidemic is remote. This is because most of the cases of relapsing malaria in our returning troops are due to *Plasmodium vivax*, the tertian type. The reason for the preponderance of this species in the relapsing cases is that it is more difficult to produce a permanent cure in this type of infection than in others. Malaria due to *Plasmodium vivax*, however, is not considered to be especially dangerous as a source of widespread disease in this country because experience in the past shows that serious epidemics of malaria are practically always due to *Plasmodium falciparum*, the subtertian or estivo-autumnal type. It is this latter type which predominates in the tropics.

The third problem, that of prompt recognition and treatment of malarial relapses, resolves itself primarily as a function of the private physician. Many physicians of the United States, particularly those in the northern sections, have had practically no experience with malaria from the diagnostic, therapeutic or public health aspects. If the physician fails to recognize cases of relapsing malaria, therapeutic measures may be delayed until the patient is in serious condition. Delay in therapy is especially hazardous to the patient suffering from estivo-autumnal malaria with cerebral involvement. The public health aspect of delayed recognition of these cases is important, as this delay will greatly aid in spreading the disease to other individuals. To counteract this gap in experience and knowledge, an extensive educational program is necessary to familiarize the physicians of this country with the protean manifestations of malaria and to keep them constantly aware of the possibility of these cases falling into their hands. After the war this situation will be alleviated considerably by the return of thousands of physicians who have had extensive experience in tropical diseases during their military services. These physicians undoubtedly will contribute greatly to increased efficiency in the practice of tropical medicine throughout the country.

Filariasis constitutes another chronic disease which is a vexing prob-

lem to the military medical personnel. The term "filariasis" in a broad sense includes several categories of parasitic nematode infestations. This discussion is limited to that form due to *Wuchereria bancrofti*. In this disease the adult worms live in the circulatory or lymphatic systems, the connective tissues or the serous cavities. The adults produce certain small larval forms, called *microfilariae*, which commonly invade the circulating blood or lymph spaces.

The seriousness of the filariasis problem lies in the fact that, while it does not cause large numbers of troops to become physically unfit for military duty, it does produce profound mental disturbances in the men affected with this disease. Thus the primary problem in filariasis is one of proper psychotherapy.

These important psychiatric problems arise because the men have seen in the native population horrible examples of long-standing and neglected cases of filariasis with extreme degrees of devastating elephantiasis and tremendously deforming scrotal involvement. Thousands of our troops have been living and fighting in hyperendemic areas of filarial disease, and a large number of these men have been infected with *microfilariae*. When the acute lymphangitis and lymphadenopathy associated with early filariasis develop, these men immediately conclude that their physical state ultimately will be the same as that of the natives they have seen. This naturally produces a profound sense of mental depression. Many write home to break engagements, fearing they will infect their future wives with the same disease. They write to their families saying they can never return home or lead normal lives because they have contracted a loathsome disease. These men tend to become chronic hospital invalids even though their physical condition may be steadily improving.

It is self evident then that the first and most important form of therapy is to change the mental attitude of these men. They must be reminded that the natives they have seen have lived under unhygienic conditions, and constantly have been reinfected with *microfilariae* over a period of many years. They must be reassured emphatically that since they have been removed from endemic areas no further infection will take place. They must be reassured constantly that probably no progressive or disfiguring elephantiasis or scrotal deformities will develop. Many hundreds of men who presumably have filariasis have been returned to this country. It is much better psychologically to keep these men in barracks and to refrain from hospitalizing them unless such a procedure is absolutely necessary. A series of graduated physical exercises is prescribed for them, and in the majority of cases the men are soon able to return to full duty. Many of them have married and the number of pregnancies normally expected has ensued from these marriages.

Continued observation of these patients indicates that the physical signs of disease are disappearing. Extensive lymphadenopathy has not been a prominent feature in the majority of cases. Clinical evidence

would lead to the conclusion that many of the adult worms are disintegrating. The diagnosis in the great majority of cases has been made on the history of exposure in a hyperendemic area with the subsequent development of lymphangitis and lymphadenopathy. Biopsies of acutely involved lymph nodes have been performed in a few cases and the adult worms have been identified. This procedure has been abandoned, however, as it leads to extensive inflammation in the lymphatics. As far as could be ascertained at the time of preparation of this paper, circulating microfilariae have not been found in the blood of any of these patients who have filariasis. It is true that in many of these instances the infection had not been present long enough to allow the demonstration of microfilariae in the blood stream. However, the complete absence of larval forms in the blood of every one of these patients, in spite of extensive search, adds another bit of evidence to support the conclusion that the disease will regress rather than progress in our returning men.

The possibility of filariasis again becoming established in the United States as a result of infection spread from our returning military personnel appears extremely remote. This is in spite of the fact that complete development of the larval forms of *Wuchereria bancrofti* has been observed in thirty-two different types of mosquitoes, and that *Culex fatigans*, the most common vector, is found in our country. For many years an endemic focus of filariasis existed at Charleston, South Carolina, and microfilariae could be found in an appreciable number of the inhabitants of this locality. At the present time this region is practically free from this disease. This focus of infection apparently arose from importation of slaves from Africa who were heavily infested with microfilariae. As a suitable mosquito vector was present, the disease continued to be active for many years, but because of improved general hygienic conditions and mosquito control measures the infestation gradually has died out.

It does not seem likely then that new endemic areas of filariasis will be set up in the United States in view of the fact that, up to the present time at least, there has been complete absence of microfilariae in the returned cases. If at a later date microfilariae do appear in these men it seems likely that the public health authorities with modern methods of mosquito control available will be able to prevent any spread to the general population.

Bacillary dysentery has been of some concern to members of our armed forces. Several epidemics have occurred in army camps in this country and in Africa. Fortunately, chemotherapy with sulfonamide drugs has proved extremely effective in curing the acute phases of the disease and there has not been a great amount of resulting military disability. Past experience with this disease tends to indicate that a certain proportion of patients who have active disease and also some of the asymptomatic carriers will harbor the organism for several years. Therefore, it is highly probable that new and more

potently virulent strains of the bacillus will be imported into the United States with returning troops. There is a possibility that these highly pathogenic strains might give rise to postwar epidemics, especially in institutions such as mental or convalescent hospitals, and in army camps. This potential hazard can be minimized by strict attention to maintaining efficient conditions of general sanitation and personal hygiene.

Another form of dysentery which is of military and civil importance is that caused by the presence of *Endamoeba histolytica*. This is by no means solely a tropical disease, as a considerable percentage of all individuals in the United States have been shown to harbor this organism. The fact remains that symptoms of *amebiasis* are more frequent and usually much more severe in tropical areas than they are in temperate zones. The chance of infection in the troops fighting in the most forward war zones is great because the necessity of hurried treatment of the drinking water may allow the cyst forms of the organism to pass through whatever process is used to render the water potable.

It is well known that different strains of *Endamoeba histolytica* vary greatly in their pathogenic capabilities. It is possible that there is a definite potential danger in the importation of new strains of this protozoal organism. This danger is heightened by the fact that the incubation period may be extremely long. Another danger is that the disease may become chronic and almost asymptomatic in undiagnosed or inadequately treated cases. Persons so affected can become a source of infection to their families and to larger groups with which they may come in contact. However, the medical profession has become much more cognizant of this type of dysentery since the Chicago epidemic of 1933 and the danger of *amebiasis* becoming much more widespread than it is at present is probably not particularly grave.

Trypanosomiasis possibly may be acquired by our troops stationed in two different areas. The African form of the disease, which is due to the presence of *Trypanosoma gambiense*, is found in equatorial Africa where many of our air transport lines have been placed. Men stationed there may acquire the infection without any clinical symptoms of disease until after return to the United States. Any spread of this form of the disease remains a relatively remote possibility, as the necessary vector, the tsetse fly, occurs only in Africa. Rigid vigilance in the spraying of airplanes and in quarantine inspection should prevent the establishment of the tsetse fly in the American tropics. Greatly encouraging results have followed the treatment of early cases of African trypanosomiasis by use of two new arsenical drugs, namely, melarsen oxide and a compound known as "70A." It appears therefore that we have little to fear from this disease.

American trypanosomiasis, due to *Trypanosoma cruzi*, might occur in personnel sent to Central or South America. This disease probably

will not become a serious problem because this particular form of trypanosomiasis usually is mild in adults. Cone-nosed bugs and some types of wild rodents in the southwestern United States harbor *Trypanosoma cruzi*, but as yet no naturally occurring cases in human beings have been reported.

Leishmaniasis is a chronic protozoal disease to which many of our troops undoubtedly are being exposed. It occurs in a visceral form, kala-azar, in the Mediterranean region, parts of India, northern China and in northeastern Brazil. The cutaneous form may be found in two main regions, one in North Africa and the Near East and the other in South and Central America. Scattered cases of leishmaniasis probably will occur in men returning from any of these parts of the world. The disease should not produce any serious postwar problems as the vector necessary for its propagation does not occur at the present time in our country.

Schistosomiasis is the only trematode infestation which is of sufficient potential danger to warrant discussion. Troops situated in areas where schistosomiasis is endemic may acquire this disease by immersion in water containing the infected snails. The larvae in the water are able to penetrate the skin even though the men so exposed are fully clothed. It is known that there is considerable specificity of the snails which are the intermediate hosts of these parasites. There is no definite proof that a species of snail exists in the United States which is capable of acting as an intermediate host in this particular disease. We do know that there are schistosomes of lower animals present in our country and the larvae of these forms are capable of producing a dermatitis in human beings, the so-called swimmers' itch. In view of this fact, there may be snails that are capable of acting as intermediate hosts in human schistosomiasis. If so, this infestation might possibly spread to the civilian population. This phase of the problem needs further study.

The possibility of importation of a few cases of *leprosy* is a problem which may assume undue importance in the minds of the civilian population because of the distorted ideas which most people entertain concerning the danger of this disease. A small number of cases of leprosy may develop among those men who have come into intimate contact with leprous natives. Clinical evidence of infection may not develop for years after their return to this country. We need not fear any wholesale spread of the disease because of these individual cases however, as experience with the Scandinavian cases brought to Minnesota years ago indicates that leprosy has a strong tendency to disappear spontaneously in most parts of the United States. Endemic foci of leprosy still remain in some regions of Texas, Louisiana and Florida, but the disease probably will not extend beyond these limits, except for occasional scattered cases of unexplained epidemiologic etiology.

Coccidioidomycosis is a fungous disease which, while not a tropical disease, is worthy of mention as a possible postwar problem. The

occurrence of this infection is confined practically entirely to the United States, and the endemic foci occur in California, Arizona and Texas. An especially large number of cases apparently originate in the San Joaquin Valley in California where several army camps have been located. Because the disease is apparently acquired by inhalation of dust containing spores, thousands of nonimmune individuals stationed in these areas for military maneuvers have been exposed to the infection. Thus, it is possible that there may be a great increase in the number of cases occurring throughout the country as these men are demobilized or discharged. Coccidioidomycosis gives rise to a symptom complex which may be difficult to diagnose at times, and hence the medical profession must be constantly aware of the possibility of encountering this disease. There is apparently no danger of the condition assuming widespread epidemic proportions as there is, evidently, no mechanism of direct transmission from person to person.

CONCLUSIONS

1 Since the men and women of the armed forces of the United States are scattered over more widespread and far-flung areas of the earth than ever before in our history, they are being exposed to, and are being infected with, a greater variety of tropical diseases than ever before.

2 The importation of these diseases in our returning military personnel will present some postwar problems in medical practice, however, the dangers of widespread epidemics of these diseases extending into our civilian population have been for the most part greatly exaggerated.

3 The most important source of potential danger in the importation of these tropical diseases probably lies in the introduction of new and highly pathogenic strains of parasites which already exist in the United States, together with the importation of new insect vectors of diseases which have never before been present in our country.

4 The Army, Navy and United States Public Health Service are fully cognizant of these potential dangers and have organized new and rigid quarantine services to control as far as possible the importation of these diseases by military traffic.

5 The general medical profession is becoming better instructed in tropical diseases and the practice of good tropical medicine will be further bolstered by the return to private practice of thousands of young Army and Navy physicians who have had considerable training and experience in dealing with diseases of the tropics.

PENICILLIN METHODS OF ADMINISTRATION AND DOSAGE

WALLACE L. HERRELL

LOCAL APPLICATION

CRUDE broth filtrates of cultures of *Penicillium notatum*, which contain penicillin, can be applied locally. This form of local treatment is of greatest value to those physicians who do not have available the more purified preparations of penicillin. These broth filtrates containing penicillin may be applied every few hours to infected lesions of the skin and soft tissue.

Either the sodium or the calcium salt of penicillin can be used for local treatment. The calcium salt is more satisfactory for this purpose than the sodium salt, particularly if the preparation is used dry and is applied to infected surfaces. The sodium salt in the dry state may cause local irritation and pain. Solutions of either the sodium or the calcium salt may be employed for local treatment of wounds that involve bone and soft tissue. They may also be used in the treatment of infections involving mucous membranes or certain body cavities (pleural space and joint cavities) as well as the eye. For this form of application physiologic saline solution or aqueous solution containing 500 to 1,000 Oxford units of penicillin per cubic centimeter is suitable. It is important to emphasize that solutions of penicillin are to be used for purposes of instillation and not for irrigation. If a solution of penicillin is used for irrigation the material does not stay in contact with the infected surface long enough to permit bacteriostatic activity.

For local treatment, penicillin may be applied in combination with sulfonamides or in the form of a cream. A suitable combination contains approximately 5,000 Oxford units of penicillin per gram of the sulfonamide. Sulfanilamide and sulfathiazole are the sulfonamides of choice for this purpose. It should be pointed out, however, that the local use of a penicillin-sulfathiazole preparation is not desirable in the treatment of infections involving the central nervous system. It is well known that sulfathiazole may produce irritation when it comes in direct contact with brain tissue.

When penicillin is incorporated into a cream for local use, it is recommended that the final preparation contain between 250 and 500 units of penicillin per gram. While penicillin may be used successfully in the local treatment of severe inflammatory lesions, the best results are more likely to be obtained when local therapy is combined with systemic penicillin therapy.

INTRAMUSCULAR ADMINISTRATION

There are several methods available for the intramuscular administration of penicillin. The substance may be administered in saline solutions every three hours or it may be administered at longer intervals if penicillin is incorporated into some substance that tends to delay its absorption and therefore prolong its action. Penicillin may also be administered by the continuous intramuscular method.

When penicillin is administered intermittently in physiologic saline solutions, 10,000 to 20,000 Oxford units are dissolved in 2 c c of the sodium chloride solution. The injections are made every three hours, day and night. It is important to keep the size of the inoculum small in order to reduce the local discomfort attending the injection. A standard 22 gage intramuscular needle $2\frac{1}{2}$ inches (about 6 cm) long is the most desirable for making these injections. Larger needles tend to increase the pain incident to the injection. Local irritation, however, may occur following these injections but serious difficulties are not, as a rule, encountered. One disadvantage of this method lies in the fact that at least eight injections are required in every twenty-four hours. Furthermore, the concentration of penicillin in the blood rises rather sharply during the first hour following intramuscular administration and then falls to a low value during the hour before the next injection is made. Sharp rises and falls in the concentration of an antibacterial agent in the blood are not, as a rule, desirable in the treatment of bacterial infections. This is particularly true in the presence of severe infections.

Morgan and his colleagues described a continuous intramuscular drip method for administration of penicillin. As much as 100,000 Oxford units of penicillin may be administered every twenty-four hours by this method. The entire amount to be used for the twenty-four hour period may be dissolved in a liter of physiologic saline solution and the rate of flow adjusted to permit the administration of this amount in twenty-four hours. According to Morgan and his colleagues, this method maintains a constant level of penicillin in the blood. Furthermore the administration can be accomplished with comparative freedom from pain on the part of the patient. The disadvantages of this method include the danger of local infection and abscess as well as the possibility that the total intake of fluid may thereby be restricted.

McAdam and his colleagues also have reported on this same method of administration. These investigators used 100,000 Oxford units per day in 100 c c of solution. When this method is employed, the rate of administration is regulated so as to deliver 100 c c in twenty-four hours (approximately 4 c c per hour). Under certain conditions this method of administration may be found very satisfactory.

An important contribution in connection with the intramuscular administration of penicillin is to be found in the report by Romansky

and Rittman These investigators examined the possible use of beeswax and peanut oil as a vehicle for prolonging the action of penicillin Mixtures containing as much as 6 per cent beeswax in peanut oil were used To these mixtures were added varying amounts of penicillin It has been found that following intramuscular injection of this material, made to contain as much as 100,000 Oxford units per cubic centimeter, adequate concentrations of penicillin can be maintained in the blood for twelve hours or longer Penicillin may be present in the urine for twenty to thirty-two hours following this method of administration This is an exceedingly important addition to the methods of administering penicillin In the treatment of certain conditions wherein long periods of administration of penicillin are not necessary (gonorrhea, pneumonia and so forth), it may be possible to administer a complete course of treatment by means of a single intramuscular injection of the beeswax-peanut oil preparation This method also may prove of value in the treatment of certain chronic infections wherein delayed absorption and prolonged action are desired

The nonhygroscopic calcium salt of penicillin is the preparation of choice for addition to these mixtures of beeswax and oil Such preparations, in addition to prolonging the action of penicillin, are fairly stable and may be kept at room temperature for a considerable period without giving evidence of loss of potency If available, sesame oil is as good as, if not better than, peanut oil in the preparation of these mixtures containing beeswax and penicillin Beeswax should not be mixed with animal oils as a vehicle for penicillin If animal oils are employed, oil tumors are likely to develop after multiple injections While beeswax-oil preparations are of value in the treatment of certain conditions, it is exceedingly important to use other methods in the treatment of overwhelming infections wherein immediate high concentrations of penicillin in the blood are desirable and are attainable immediately by intramuscular or intravenous administration

Other studies on efforts to prolong the action of penicillin following its intramuscular administration have been reported by Trumper and Hutter The principle that they employed is that chilling slows circulation in and around the site of an intramuscular injection Therefore, one or two hours before a single, large dose of penicillin in physiologic saline solution was to be administered intramuscularly, an ice bag was applied at the site of injection and it was left in place for five to twelve hours after the injection By use of this method, effective concentrations in the blood were maintained for at least five hours, as compared with two and a half hours when single doses were administered without chilling The investigators obtained satisfactory results in treatment of patients suffering with gonorrhea when using single injections of 50 000 units of penicillin They concluded that, if chilling was employed, bacteriostatic concentrations of penicillin could be maintained by giving two or three, instead of eight

to twelve, intramuscular injections over a period of twenty-four hours

Trumper and Hutter also pointed out that application of the ice bag in advance of injections of penicillin rendered the administration painless. In my experience, the application of an ice bag one-half to one hour before intramuscular injections are made is an exceedingly effective method for reducing the amount of pain at the site of local injection.

When intramuscular injections are to be made, it is also important that the injection be made by means of a sudden thrust of the needle into the tissues. Furthermore, it is important that the site of injection be changed frequently. The view is commonly held that penicillin should be administered only into the buttocks. However, it may be administered also into the deltoid muscles, thereby increasing the number of sites of injection.

INTRAVENOUS ADMINISTRATION

Penicillin may be administered intravenously by means of repeated single injections or by means of the continuous intravenous drip method. When penicillin is administered by the former method, it disappears from the blood stream even faster than after a single intramuscular injection. Furthermore, if penicillin is administered by single intravenous injection every three hours, eight separate venipunctures must be made each day. While this method has been used with satisfactory results, it is not the method of choice for intravenous penicillin therapy.

The continuous intravenous drip method best maintains a constant level of penicillin in the blood. It is the method of choice in the treatment of severe overwhelming infections such as bacteremia. The technic is as follows: Half of the twenty-four hour dose of penicillin is dissolved in 1 liter of isotonic solution of sodium chloride. If the use of sodium chloride is undesirable, the material can be dissolved in a 5 per cent solution of dextrose made up in distilled water. However, the continuous administration of dextrose may of itself at times produce venous irritation. At the Clinic, therefore, we dissolve the material in dextrose only in those cases in which the use of sodium chloride is undesirable. Next, an 18 gage Lewisohn transfusion needle is inserted deeply into the vein, usually a vein of the arm, and is anchored with adhesive plaster. Use of veins on the dorsal surface of the hand or on the lateral aspect of the forearm allows the hand to be kept in pronation and renders this method of administration much less uncomfortable than when the material is administered with the arm in supination. A simple arm splint or bandage is applied to keep the arm in position. This method is tolerated well by the patient and renders the administration of penicillin fairly comfortable. It avoids eight separate intramuscular or intravenous injections in twenty-four hours. Some patients who receive penicillin in this fashion may sit up

at times during the course of the injection. It has been possible to administer penicillin without changing the needle or disturbing the apparatus in some instances for as long as eight days. Veins in the feet or legs can be used for this method of administration but the veins of the arm are preferred because complications following occasional venous irritation or thrombosis are considerably less severe if the veins affected are in the upper rather than in the lower extremity.

From what has just been written, it is evident that local venous irritation at the site of injection may attend the use of the continuous intravenous drip method. Parenthetically, it may be said here that such irritation seems especially likely to occur with certain batches of penicillin which may contain impurities. Careful inspection of the intravenous apparatus and changing the site of injection at the first sign of irritation usually are sufficient to cope with this difficulty. Although my colleagues and I have administered penicillin for as long as eight days through the same vein and into the same site of injection, it is often necessary to change the apparatus every few days. In my experience, venous irritation does not occur in more than 5 to 10 per cent of cases. In this connection should be mentioned the possible inclusion of heparin in intravenous infusions as a means of preventing thrombosis or venous irritation, which may occur when the intravenous drip method is used. This use of heparin was suggested by Martin, who found that 3 units of heparin per cubic centimeter of solution of penicillin made it possible to give the required amounts of penicillin without incident. He further pointed out that when infusions are given at the rate of 35 drops per minute, it would not seem possible to administer enough heparin to affect clotting time materially.

Now, to return to the technic of administration. Initially, 100 c.c. of the material is allowed to run into the vein at a fairly rapid rate. Following this the rate of injection is regulated to 20 to 30 drops a minute. The second liter is attached to the continuous intravenous system eight to ten hours later or whenever the material in the original bottle has been used. Repeated venipuncture is avoided by allowing saline or dextrose solutions to drip in slowly if, for any reason, administration of penicillin is unintentionally interrupted.

I have used as a rule, no more than 100,000 Oxford units per day and, in many instances, 40,000 units per day for intravenous therapy. Obviously, when increased supplies of penicillin are available, the problem of dosage may become of less and less significance. In our early work with penicillin low doses were employed in order to spread a small supply of penicillin as far as possible. If subsequent experience indicates that the hazard of delayed recurrence of the condition being treated is increased by using low dosage, obviously the amounts used must be increased. I consider, however, that 100,000 units per day is probably the maximal amount of penicillin necessary for treatment of those infections most commonly encountered. Delayed recurrences

in the presence of metastatic lesions may occur at times regardless of the amount of penicillin used

As I have already mentioned, the continuous intravenous drip method is the one of choice in the treatment of severe, overwhelming infections such as bacteriemia. Penicillin should be given by this route at least for the first few days of treatment. Under certain circumstances, the intermittent intramuscular method is entirely satisfactory. On the other hand, it is my impression that nearly twice as much penicillin is required for satisfactory intramuscular treatment as is required when the intravenous drip method is employed. That this is the case seems evident also from the report by White and others. They declared that in their opinion 100,000 units of penicillin, given by the intravenous drip method, are as effective as 200,000 units administered by the intramuscular method.

SUBCUTANEOUS ADMINISTRATION

Penicillin can be administered intermittently or continuously by the subcutaneous route. However, absorption of material administered subcutaneously is erratic. Moreover, concentrated solutions of penicillin may at times prove irritating when given subcutaneously. It appears, therefore, that the intravenous or intramuscular method of administration is preferable to the subcutaneous method.

INTRATHORACIC ADMINISTRATION

In the treatment of suppurative intrathoracic disease such as empyema, it often is desirable to supplement systemic therapy with instillations of penicillin into the pleural space. In some instances, empyema can thus be satisfactorily treated without resorting to surgical drainage. For intrathoracic treatment, 40,000 to 50,000 units of penicillin are administered daily. The amount to be used should be dissolved in 40 to 50 c.c. of physiologic saline solution and instilled directly into the pleural space following thoracentesis. It is recommended that this procedure be carried out once every twenty-four to forty-eight hours.

INTRA-ARTICULAR ADMINISTRATION

My colleagues and I⁵ have reported studies which indicate that following systemic administration of penicillin antibacterial amounts of the material reach the fluid of inflamed joints. This is also true of the fluid of joints which are not inflamed. The amount of penicillin present in the joint fluid usually will be approximately half that found in the blood. Antibacterial amounts of penicillin may reach the joint fluid following intramuscular or intravenous administration. It is often desirable, however, to supplement systemic therapy by means of instillation of penicillin into the affected joints. This can be accomplished without any serious effects. Ten thousand to 20,000 Oxford units of

penicillin dissolved in 10 c.c. of isotonic saline solution can be instilled into infected joints after aspiration has been performed. Since penicillin remains in the structure for at least twenty-four hours, it is not necessary to repeat the injection oftener. The material can be administered every day or every other day for several times.

INTRATHECAL ADMINISTRATION

It is generally agreed by most investigators that penicillin does not readily diffuse into the cerebrospinal structures following its systemic administration. This appears certainly true of subjects suffering with certain diseases, such as syphilis, involving the cerebrospinal structures. It seems true, also, of the patient who, after being subjected on therapeutic indications to administration of penicillin and spinal puncture, yet is found to be normal. Although small amounts of penicillin may reach the cerebrospinal fluid in certain types of infections (acute meningitis for instance) it seems essential to supplement systemic therapy by daily instillations of 10,000 to 20,000 Oxford units of penicillin directly into the spinal canal. At least this should be done during the early period of treatment of severe diseases involving the spinal cord and meninges. This procedure, as a matter of fact, can be carried out for a considerable period without producing any important reactions. The amount of penicillin administered should be dissolved in 10 c.c. of isotonic solution of sodium chloride. Either the sodium or the calcium salt of penicillin has proved satisfactory for this form of treatment.

Five thousand to 10,000 units of penicillin can be instilled also once or twice daily into the ventricular system of the brain if small tubes have been left in place for this purpose at the time some surgical procedure is carried out.

INFUSION OF PENICILLIN BY WAY OF THE BONE MARROW

A satisfactory method for administration of various therapeutic agents by way of the bone marrow has been described by Tocantins and O'Neill. The sternum or clavicle can be used and, in children, the tibia or femur has been employed. It has been found possible to administer as much as 1 liter of solution by this route when the infusion needle was left in place for as long as sixteen hours. The average rate of infusion recommended by Tocantins and O'Neill was between 0.4 and 9 c.c. per minute. Likewise, Turkel and Bethell also have described a satisfactory instrument and technic for administration of fluids through the bone marrow.

Since either glucose or salt solution can be administered by way of the bone marrow, Morgan and his colleagues used this method for administration of penicillin in these solutions. It appeared from the report of Morgan and his colleagues, that as much as 46,000 units of penicillin could be administered in nine hours by this route. This

method, however, is not recommended except under very unusual circumstances, for instance, when suitable veins are not available or when, for any reason, as in the presence of extensive burns, the intramuscular or intravenous method is not considered practicable

PENICILLIN SNUFF

Snuff containing 5 parts of penicillin by weight, 5 parts of menthol and 90 parts of lycopodium has been recommended by some investigators³ The material is administered by this route as often as every four hours Except in the most superficial types of infections in the nose, however, this method is not likely to be followed by satisfactory results unless, perhaps, systemic therapy also is employed

PENICILLIN AS AN INHALANT

It is evident from the report of Bryson and his colleagues that penicillin can be used as an inhalant It is so employed by having the patient breathe nebulized penicillin according to the standard procedure recommended for this purpose When this form of treatment is used (bronchitis and bronchiectasis), patients may inhale varying amounts of penicillin at regular intervals throughout the day One cubic centimeter of physiologic saline solution, containing 2,500 Oxford units of penicillin, can be nebulized and inhaled by a patient over a period of ten minutes This procedure can be carried out as often as three times an hour throughout the day, excluding time out for eating and sleeping As much as 75,000 to 80,000 Oxford units can be administered by this method This procedure must not be confused with vaporization methods, wherein the heat that is employed is likely to inactivate penicillin

ORAL AND INTRACOLONIC ADMINISTRATION

At present, the oral administration of penicillin is not entirely satisfactory and is not generally recommended The hydrochloric acid in the stomach will destroy most of the penicillin that is administered orally On the other hand, it was evident from the report of Free and others that at least some penicillin reaches the general circulation and is excreted in the urine following the oral administration of large doses (100,000 Oxford units) of penicillin to human subjects who had fasted for three to six hours before the penicillin was administered Enteric coating to protect penicillin against gastric acidity does not satisfactorily solve the problem since, when enteric coating is employed, penicillin may find its way into the large intestine, where it is inactivated by certain bacterial enzymes present there If a patient presents complete achlorhydria, penicillin can be administered by mouth and absorbed into the general circulation in amounts sufficient to justify this method of administration This method may be of value in the treatment of patients who have achlorhydria, therefore, if other acceptable methods are not practicable Whether pen-

icillin can be administered successfully by the oral route^{2, 6, 7, 9} to human beings, alone, combined with antacids or in various vehicles, will depend on further trials

The intracolonic administration of penicillin is of no value for reasons which I have already mentioned.

OBSERVATIONS ON CHEMOTHERAPY OF CLINICAL AND EXPERIMENTAL TUBERCULOSIS

H CORWIN HINSHAW and WILLIAM H FELDMAN

THE need for an effective chemotherapeutic agent in treatment of clinical tuberculosis has led to extensive research, especially since the time of Ehrlich. While many compounds, especially gold salts, have been recommended and have found temporary clinical favor, the evidence for true therapeutic effect has not been convincing in any instance. The evidence submitted was subject to the unavoidable inaccuracies of clinical observation on a disease that has widely divergent clinical trends and so frequently tends to heal spontaneously in human beings. Prior to 1940 none of the alleged chemotherapeutic aids had demonstrated an ability actually to arrest the progress of tuberculosis experimentally induced in guinea pigs. The first compound that evinced the ability actually to arrest the progress of experimentally induced tuberculosis in guinea pigs was sodium p,p'-diaminodiphenylsulfone-N,N'-didextrose sulfonate (promin)⁶.

The value of animal experimentation in the guidance of clinical research in treatment of infectious disease has been clearly demonstrated in recent years. Most, if not all, of the presently favored chemotherapeutic agents, which have proved to be so effective in treatment of many acute infectious diseases, have been discovered through methods of animal experimentation. A very close correlation has been shown to exist between the effect of most chemotherapeutic drugs on experimental infection induced in animals and the corresponding clinical disease naturally occurring in man. The correlation is not nearly so close between in vitro test tube methods and human disease. Because of this well-established value of animal experimentation in such problems, we believe that experimental tuberculosis of guinea pigs must continue to be the proving ground for any drugs that may be proposed for human administration.

The task of testing prospective chemotherapeutic drugs on experimental tuberculosis is infinitely more difficult than in the case of many acute diseases. Streptococcal and pneumococcal infections, for example, may be studied in a small animal such as the mouse and the disease produced may develop in such brief time that a great deal of information may be obtained within a few days with a very small amount of drug. In the case of tuberculosis the disease requires weeks or months to develop and the smallest practicable animal is the guinea pig, requiring an expenditure of time and drug much greater than is required in the case of streptococcal or pneumococcal infection. It appears probable, therefore, that a period of years will be required

to achieve full understanding of the therapeutic potentialities of any large number of compounds. During the past five years only a few score of compounds have received adequate study in experimental animals and of these only four have reached the stage of extensive study on clinical tuberculosis, promin, diasone, promizole and streptomycin.

PROMIN (SODIUM P P-DIAMINODIPHENYLSULFONE-N N'-DIDEXTROSE SULFONATE)

It has been clearly shown⁷ and repeatedly confirmed^{1 8 10} that promin has the power of inhibiting the development of lethal tuberculosis in the experimentally infected guinea pig. The duration of life of treated animals may be extended, perhaps indefinitely, so long as treatment is continued. During this period the animals appear to remain in perfect health. Treatment has been continued for as long as one year, long after all untreated control animals have succumbed. At necropsy, treated animals frequently have no recognizable lesions of tuberculosis when observed grossly or there may be residual indolent lesions in the regional lymph nodes adjacent to the sites of subcutaneous inoculation, in the tracheobronchial lymph nodes and rarely in the viscera. Microscopic examination, however, will frequently reveal the presence of small stabilized or healing lesions, which would not have been observed had sections not been made. In such residual lesions the histologic picture may be that resembling the various steps of healing, including resolution, fibrosis, encapsulation and even calcification. Caseation necrosis is rarely seen and the tubercles observed are commonly of the so-called hard or epithelioid type. This is in striking contrast to the much more extensive and obviously progressive destructive lesions uniformly seen in all untreated control animals. It is important to emphasize that animals that have been treated even for prolonged periods with promin and appear to possess only lesions of healing type or even those that have no demonstrable lesions, still harbor virulent tubercle bacilli, which can be recovered when emulsions of spleen are used for the inoculation of other guinea pigs or even by cultural methods for isolation of tubercle bacilli.

Efforts to utilize promin in treatment of clinical tuberculosis have been under way during the past four years.^{3 8} It was soon revealed that human beings do not tolerate promin in doses comparable to those that produce the therapeutic effect in experimental guinea pigs. In deed, more than a half of all patients are unable to take even small doses of promin, either because of uncomfortable reactions or because of the development of mild to moderate anemia when treatment is extended over many weeks or months. The poorest drug tolerance is demonstrated by those failing patients who are most in need of some chemotherapeutic aid. Experience has suggested to us that patients in terminal phases of pulmonary tuberculosis tolerate promin so poorly that the drug is definitely contraindicated because it contributes to

the discomfort of such patients and in no instance has it appeared to reverse the downward trend of desperately ill patients. In such instances the pathologic character of the disease in human beings is quite different from that of recently infected tuberculous guinea pigs. More suggestive effects have been noted in recent lesions of pulmonary tuberculosis, especially those known to have existed for only a few weeks and among patients whose general condition is reasonably good. We have had the opportunity of observing only a moderate number of such patients, those who have tolerated promin in adequate dose to yield a blood level in excess of 2 or 3 mg per 100 c c have shown encouraging progress. It is exceedingly important to indicate, however, that in all instances the lesions of these patients have been such as tend to resolve spontaneously and sometimes very rapidly under the influence of rest in bed alone. Because of this we have not felt justified in drawing any conclusion as to the therapeutic efficacy of promin in cases of pulmonary tuberculosis.

Promin has been administered by the oral route to all the experimentally infected guinea pigs in our studies and also we have chosen to administer it by the oral route over prolonged periods to those patients who have received this drug. It is also possible to administer promin parenterally and, when the drug is so given, the uncomfortable and potentially hazardous toxic results are rarely noted. Zucker, Pinner and Hyman¹² have attempted to treat clinical tuberculosis by administering promin in large doses over brief periods by the intravenous route but their results were wholly disappointing. It seems probable to us that orally administered promin is modified, perhaps by hydrolysis, to produce some compound resembling diaminodiphenylsulfone but that when administered intravenously the drug is excreted too rapidly to undergo similar change.

Somewhat more encouraging results have been noted in a small number of patients who had extrapulmonary tuberculosis, especially osseous lesions with draining sinuses.¹¹ Here, again, the small number of cases and the lack of an adequate control series have made it impossible to draw definite conclusions. It has also appeared doubtful to us if closely controlled clinical studies should be carried out with a drug such as promin, which is so difficult to administer over prolonged periods by the oral route. We have directed our efforts toward the study of less toxic compounds in recent months.

A few patients who had tracheobronchial tuberculosis of ulcerating type have received promin, either by repeated supraglottic intratracheal administration or, more recently, by inhalation of nebulized promin solution.^{2 3 4 11 12} It has been noted that promin is well tolerated when administered in this manner and sufficient improvement has been noted to suggest the possibility that more extensive study of this approach to treatment of these difficult lesions could be carried out. This will be possible in the near future when the promin solution is made available commercially.

Promin may also be applied topically to superficial lesions of tuberculosis such as draining sinuses in the thoracic wall, sinuses from tuberculous lymphadenitis and possibly some types of cutaneous tuberculosis. The most convenient method of applying promin to these lesions is in the form of a jelly, similar to that which has been under trial in England.¹¹ Results have been sufficiently suggestive to lead to the early appearance of this preparation, also, on the market. Promin jelly applied topically rarely produces any toxic manifestation whatever. It is anticipated that this will receive wide study within the next year or two, after which more definite conclusions may be reached.

DIASONE (DISODIUM FORMALDEHYDE SULFOXYLATE DIAMINODIPHENYL SULFONE)

Diasone is very similar to promin chemically, although lacking the glucose molecule present in promin and with a change of valence of the sulfur atoms that are attached to the end chains. It should be anticipated that diasone, like promin, should undergo hydrolysis in the human body to some compound resembling diaminodiphenylsulfone. Diasone has been studied in experimental tuberculosis of guinea pigs and possesses very similar properties to those described for promin in previous paragraphs. We have had no direct personal experience in the administration of diasone to patients who had clinical tuberculosis and results that have been reported are conflicting. Several groups are now investigating diasone clinically and it is anticipated that more information will be available before many months. It appears wise to withhold judgment until some concerted opinions have been expressed.

Diasone was brought into general prominence by the appearance in lay publications of uncritical opinions, which were widely disseminated and, of course, eagerly seized on by many victims of tuberculosis, some of whom have been disillusioned. The most unfortunate result has been the tendency of such patients to refuse acceptance of known effective treatment for tuberculosis especially sanatorium care and collapse therapy.

PROMIZOLE (4,2-DIAMINOPHENYL-5-THIAZOLESULFONE)

Promizole is of unusual interest because of the fact that it possesses similar properties to those already described for promin and diasone in effectively controlling the development of experimental tuberculosis in guinea pigs and especially because of the fact that its chemical structure is basically different, having a heterocyclic nucleus to the molecule, which could readily be the beginning of a new series of compounds. This interest was greatly heightened by the observation that patients were able to tolerate promizole in doses quite comparable to those administered to guinea pigs and that blood concentrations of comparable degree were noted in such patients.

Observations on promizole in cases of clinical tuberculosis have been under way during the past two years in collaboration with several other clinicians but results have not yet been published. It may be stated at this time, however, that as yet no fully convincing evidence of striking therapeutic effect has been observed in our experience.

STREPTOMYCIN

It has been shown recently⁵ that streptomycin is effective in treatment of experimental tuberculosis of guinea pigs. We and our associates have utilized streptomycin in treatment of twenty-two patients with clinical tuberculosis since December, 1944 and have not noted serious toxic effects, even after prolonged administration of large doses. Any decision as to its therapeutic efficiency must await more extensive study.

RHEUMATIC FEVER, A SUMMARY OF PRESENT DAY CONCEPTS

ARLIE R. BARNES

THE prevalence of rheumatic fever in the armed forces has emphasized again that it is a major medical problem. The decision had to be reached not to reject for military service those individuals who had had an attack of rheumatic fever provided evidence of heart disease was absent. Since an attack of rheumatic fever is evidence that the selectee is a "susceptible" and hence bears a greater than average liability of recurrence of rheumatic fever, such a plan is not ideal from a public health point of view. However, administrative problems involved in the rejection of such selectees appeared to make their exclusion impractical. The medical personnel of the armed services is confronted with the problem of diagnosis and prevention of rheumatic fever and of the disposal of those individuals who have an attack while in the service.

EPIDEMIOLOGY

Rheumatic fever occurs most commonly in childhood and adolescence, the average time of the first attack being in the seventh or eighth year of life. A distinct familial incidence is conceded, in which respect the disease is like tuberculosis. Wilson,⁷ and others have presented much evidence that heredity is a very important factor in predisposing to its occurrence. Much evidence is available that there are marked sectional and climatic differences in the incidence of rheumatic fever. The disease has a high incidence in the Rocky Mountain and New England states but fewer cases occur in the warmer southern portion of the United States. The disease has its lowest incidence in the summer months and its greatest prevalence in the cold and wet months of the year. Rheumatic fever is believed to be more common among the less favored economic groups in which the ill fed, the ill clothed and the ill housed are included. Wilson did not find this to be true and the British Medical Research Council⁸ did not find this economic factor to be of prime importance in the occurrence of the disease.

Rheumatic fever should be regarded as an epidemic disease. There is a close association of initial and recurrent attacks of rheumatic fever and infections caused by hemolytic streptococci. If careful sampling of throat cultures of new recruits reveals a high incidence of infection due to hemolytic streptococci, the prediction may be made that rheumatic fever will appear in the group in considerable incidence in from ten days to three weeks (Massell and Jones⁴). A considerable number of patients known to be susceptible to rheumatic fever and exposed to such an epidemic likewise will have a recurrence of the disease.

ETIOLOGY

At the present time the cause of rheumatic fever is unknown. Much evidence suggests a causal relation with hemolytic streptococci. Also, there is much to indicate that allergic reactions play an important role in its production. Investigators postulate an individual in a state of hypervulnerability or allergic irritability (Swift, Derick and Hitchcock⁶) or they conceive that the disease results from an allergic response of tissues which have been sensitized previously by a specific or nonspecific streptococcic infection.⁷ The occurrence of group A beta-hemolytic streptococci in respiratory infections, which frequently precede rheumatic fever, is well established according to Massell and Jones but the specific relation of these organisms to rheumatic fever awaits experimental reproduction of the disease.

DIAGNOSIS

The diagnosis of rheumatic fever presents real difficulty at times. One has to guard against the error of dismissing minor evidences of the disease with consequent failure to recognize the disease on the one hand, and, on the other, the error of concluding that rheumatic fever exists on the basis of inadequate clinical grounds with all the unfortunate consequences which such a mistaken diagnosis entails. The diagnosis of rheumatic fever probably rests on a sound basis if several of the following manifestations are present in a case (Jones²):

- 1 Carditis. Evidence of carditis is definite cardiac enlargement, significant cardiac murmurs, pericarditis or congestive heart failure. Electrocardiographic changes which include prolongation of the auriculo-ventricular conduction time, inversion of the T waves and the peculiar elevation of the S-T junction (pericarditis) are important evidence of myocardial injury and constitute corroborative evidence of carditis.
- 2 Arthralgia. Tender, red, swollen joints, particularly if there is a migratory character to their involvement, are strongly suggestive of rheumatic fever. However, as Jones remarked, in cases in which this manifestation constitutes the only symptom one must remain skeptical.
- 3 Chorea. Since chorea develops in half of the cases of rheumatic fever in which the patients are young persons and since definite evidence of rheumatic fever (Jones) eventually develops in three-fourths of the cases of chorea, this symptom is very important, when present, in corroborating the diagnosis.
- 4 Recurrence of rheumatic fever. The presence of mild symptoms of rheumatic fever occurring in an individual with a definite history of the disease or signs of rheumatic heart disease are very significant evidence for a positive diagnosis.

Not every patient who has rheumatic fever has the combined symptoms of respiratory infection with sore throat, migratory swelling and redness of the joints, chorea and fever. There are many cases in which respiratory infection and sore throat are followed only by vague

articular pains with perhaps only one or two joints involved and with little redness or swelling of a very transitory nature. This articular involvement may be so slight as to be overlooked by the patient and physician unless a high index of suspicion of rheumatic fever is entertained. A low-grade fever, which may not exceed 100°F. , may persist longer than would be expected with the usual infection of the upper part of the respiratory tract. In such cases rheumatic fever must be suspected and the patients must be kept under observation for a considerable time. This is especially important if the patient is one of a group in which an epidemic infection with beta hemolytic streptococci or an epidemic of scarlet fever is known to exist or if the patient is one of a group in which an epidemic of rheumatic fever is prevalent. When such patients are kept under observation the sedimentation rate of the erythrocytes may remain elevated, electrocardiographic evidence of delayed auriculoventricular conduction may appear and evidence of cardiac involvement in the form of significant murmurs, pericarditis and cardiac enlargement eventually may appear. Unless more suspicion is attached to these innocent attacks in young adults, many instances of rheumatic fever will be overlooked and many patients will be deprived of a proper convalescent program which would afford them the maximal protection from serious cardiac damage.

It must be emphasized that an unwarranted diagnosis of rheumatic fever should not be made. The connotation of an unwarranted diagnosis is such that, although the diagnosis later is disproved, the patient is left with a cardiac neurosis that it is next to impossible to eradicate in many instances. Since other diseases, such as rheumatoid arthritis, tuberculosis, lupus erythematosus and undulant fever, to mention only a few, may give rise to symptoms simulating rheumatic fever, observation of the patients for months or years may be required to arrive at a true diagnosis (Jones).

TREATMENT

Rest still remains the essence of the treatment of rheumatic fever. Its optimal duration is scarcely the same in any two cases but certainly it must be continued until fever and involvement of the joints disappear, until the sedimentation rate is normal and until the electrocardiographic changes have disappeared. Persistent cardiac enlargement or any evidence of myocardial failure are indications for prolonged rest.

Salicylates administered by mouth in large doses reduce the fever and relieve pain but there is no evidence that they shorten the attack. Recently, Coburn¹ has advised the intravenous administration of large amounts of salicylates with a view to maintaining a high concentration of the drug in the blood stream. His preliminary observations arouse hopes that this method may be very effective, but further ex-

perience with this type of treatment will be required to determine and establish its efficacy

PREVENTION OF RHEUMATIC FEVER

The work of Jones⁸ indicates the close relation that exists between certain outbreaks of respiratory infection in which hemolytic streptococci are concerned and the subsequent development of rheumatic fever in many of the individuals so infected. It is only by careful bacteriologic studies that the evidence of a high incidence of hemolytic streptococci in individuals with respiratory infection can be established. Once the presence of these organisms is established, segregation may be feasible. There is evidence that the spread of infection is particularly prone to occur during sleeping hours and especially when large numbers of people are sleeping in a single room. It is not known as yet whether the administration of sulfonamide drugs to groups of people known to harbor hemolytic streptococci in their respiratory passages will reduce the likelihood of contagion or prevent the occurrence of rheumatic fever subsequently in individuals so infected. However, this is an approach that is receiving careful study. Jones said that there is some evidence that the daily administration of salicylates, starting at the time of a respiratory infection with hemolytic streptococci, may in some way greatly decrease the probability that rheumatic fever will develop subsequently.

Just as susceptibility of individuals and families to rheumatic fever is an accepted fact, it also can be said that one who has had rheumatic fever is more liable to a subsequent attack. It appears, moreover, that such an individual runs his greatest hazard if he acquires a respiratory infection due to hemolytic streptococci. There are numerous reports, hard to evaluate, it is true, indicating that the daily administration of a sulfonamide drug to such an individual greatly limits such respiratory infections and hence reduces his chance of having a recurrent infection with rheumatic fever. To offset the possible advantages of such a program is the danger of developing drug sensitivity and drug fast strains so that its adoption on a large scale must await much more study of not only its effectiveness but of its possible dangers.

Some effort can be made to minimize the exposure of persons who have had rheumatic fever to respiratory infection and particularly to infections due to hemolytic streptococci. The studies of the British Medical Research Council and of Wilson indicate that recurrences are less common among persons who are well housed, well clothed and well fed. There is considerable evidence that recurrences are diminished if the patient can be moved to a warmer and possibly drier climate. This procedure has been utilized by the armed services but it is not as feasible for the civilian population for economic reasons. It is desirable that susceptible soldiers not be quartered with new recruits, among whom epidemics of respiratory infections are common in the

first few weeks after induction. Whenever possible, individual sleeping quarters or sleeping quarters with only one other person reduce the chances that a susceptible individual will acquire a respiratory infection.

INSTRUCTION OF PATIENTS WHO HAVE RECOVERED FROM RHEUMATIC FEVER

One of the gravest responsibilities that confronts a physician is the advice he gives a patient who has recovered from rheumatic fever. Physicians are seeing too many civilians, and particularly too many discharged soldiers, who have derived wittingly or unwittingly nothing but hopelessness from this advice. It is difficult to disabuse their mind of its anxieties, and without such corrective measures these individuals become confirmed cardiac neurotics and suffer far more from this neurosis than they ever will from their heart disease.

It is well to bear in mind that only a small percentage of patients who have had rheumatic fever become disabled by heart disease and succumb by mid-adult life. Since this observation applies to children and since the incidence of serious heart disease following rheumatic fever which occurs first in adult life appears to be less than it is in children, it is with these adults that one should be particularly careful that the matter is presented in a proper manner. If they recover with a heart that is normal in size, notwithstanding the fact that they may have a cardiac murmur, it should be pointed out to them that such a situation is usually compatible with a life of normal activity and usefulness provided they do not have one or more recurrent rheumatic infections. They should be warned that their special problem is the avoidance of and the meticulous care of, respiratory infections. Although physicians do not know as much about the prevention of such infections as can be hoped that the future will provide, the patients can be warned against conditions of exposure, unnecessary exposure in crowds during epidemics of respiratory infection, loss of sleep and all other unhygienic measures which are believed to lower resistance. If feasible, they may be advised that residence in the warmer or drier latitudes of the United States will afford some measure of protection. Above all, physicians have an obligation to orient the patient to his illness and its relation to his future life so that one more will not be added to the already overlarge population of neurotics.

SUMMARY

Rheumatic fever is a huge problem not only in civilian life but in the armed forces. It is a disease in which individual and familial susceptibility plays a large role. It is related to climatic conditions and is prevalent at that time of year when respiratory infections attain their greatest proportions. Although its cause is not known, there are many facts which suggest that it follows in the wake of respiratory infection due to hemolytic streptococci. The clue to the prevention of initial and recurrent attacks may lie in a more precise knowledge of

this relationship and in measures which may permit physicians to prevent rheumatic fever once they know that respiratory infections due to hemolytic streptococci are at hand. It is possible that the sulfonamide drugs, salicylates or other drugs yet unknown will be found either to limit the incidence of such respiratory infections or provide a cure for rheumatic fever itself. Certainly, more productive investigation of these possibilities is being stimulated by the problems presented in the armed services. Too much emphasis cannot be directed to the responsibilities physicians have to instruct all who have recovered satisfactorily from rheumatic fever in such a way that they do not become cardiac neurotics. Such an attitude in these patients is tragic and easily can be avoided if only a little time is taken with each patient to orient him in a proper outlook on his situation.

THE CLINICAL USE OF DICUMAROL

NELSON W BARKER

IN 1941 Link and his associates^{7 13} reported the isolation and synthesis of dicumarol [3,3'-methylenebis (4 hydroxycoumarin)] Since that time a number of reports^{1 2, 5 6} have been made on the physiologic effects of this drug on animals and human beings At the Clinic dicumarol has been administered to more than 1,000 surgical patients during the postoperative period for the purpose of preventing postoperative thrombosis and embolism and it has also been administered to more than 100 nonsurgical patients who had various types of arterial and venous thrombosis and embolism for the purpose of preventing or inhibiting the progress of their disease This report is based on the study of these patients

QUESTIONS AND ANSWERS

What is the physiologic effect of dicumarol on human beings?—Dicumarol produces prothrombin deficiency as indicated by the Quick prothrombin time test^{5 6} The prothrombin deficiency may be mild or severe depending on the amount of the drug given over a period and by the individual susceptibility of the patient to the drug As a secondary effect of prothrombin deficiency the coagulation time of the blood (Lee-White) may be, but is not necessarily, prolonged The degree of prolongation of the coagulation time does not necessarily parallel the degree of prolongation of the prothrombin time Thus the coagulation time cannot be used as an index of the effect of the drug on an individual patient Dicumarol usually prolongs the clot retraction time and elevates the sedimentation rate of the erythrocytes Some recent work¹² indicates that it may inhibit platelet adhesiveness. Otherwise the drug does not appear to have any physiologic or toxic effects on human beings Even after prothrombin deficiency of moderate to severe degree has been maintained for more than two months by administration of dicumarol, the ordinary tests of hepatic function have been found to give negative results and no untoward effects have been noted

Does dicumarol prevent thrombosis in human beings?—The evidence that the prothrombin deficiency produced by dicumarol prevents thrombosis in human beings has come largely from statistical studies of postoperative patients At the Clinic it was found that among 678 patients who had a pulmonary embolism and survived and who did not receive dicumarol 297 (43.8 per cent) had one or more subsequent episodes of thrombophlebitis or pulmonary embolism and 124 (18.3 per cent) had a subsequent fatal pulmonary embolism⁴ Among 180 similar patients who had pulmonary embolism and survived and

did receive dicumarol, only two (1.1 per cent) had subsequent thrombophlebitis or embolism and only one (0.6 per cent) had a subsequent fatal embolism. Also among 897 patients who had postoperative thrombophlebitis (or phlebothrombosis) and who did not receive dicumarol, ninety-five (10.6 per cent) had one or more subsequent episodes or extensions of the thrombophlebitis and fifty-one (5.7 per cent) had subsequent fatal pulmonary embolism.⁴ Among 138 similar patients who received dicumarol four (2.9 per cent) had more thrombophlebitis and none had fatal embolism.

Sixty-one patients who have had thrombophlebitis or embolism at some time prior to operation have been given dicumarol prophylactically and none have had thrombosis or embolism after operation. Dicumarol has been given prophylactically to 438 patients on whom abdominal hysterectomy had been performed and who had not had thrombophlebitis or pulmonary embolism. In a previous study it had been found that the risk of thrombophlebitis and embolism in these patients was 4 per cent and the risk of fatal embolism 0.7 per cent.³ No embolisms developed in the 438 patients who received dicumarol. Two of these patients had minor thrombophlebitis of the veins of the calf but only after they had left the hospital and after the prothrombin had returned to normal. The nonsurgical patients who received dicumarol had various diseases characterized by thrombosis and included patients who had thrombophlebitis or pulmonary embolism, complicating infectious diseases, blood dyscrasias, congestive heart failure and severe injuries, recurrent idiopathic thrombophlebitis, intracardiac thrombosis with arterial embolism, simple arterial thrombosis, thrombo-angitis obliterans and arteriosclerosis obliterans. In none of these cases was there any evidence that thrombosis or embolism developed during the period in which the prothrombin time was elevated as the result of administration of dicumarol.

How important is the Quick prothrombin time test as a guide to the administration of dicumarol?—The purpose of administration of dicumarol is to produce a definite but not excessive prothrombin deficiency. If as a result of administration of dicumarol the prothrombin is less than 30 per cent of normal, thrombosis will almost certainly not develop and if the prothrombin is greater than 10 per cent of normal, bleeding will almost certainly not occur. Therefore in any individual case it is necessary to keep the prothrombin between 30 per cent and 10 per cent of normal to achieve the desired effect. Patients vary considerably in their sensitivity to the drug and this variability is usually unpredictable. Furthermore the effect of dicumarol is delayed, developing twenty-four to seventy-two hours after a dose is given, and it may persist for several days after reaching a maximum. For these reasons it is absolutely necessary to do daily prothrombin time tests^{10, 11} (Quick method) on a patient who is receiving dicumarol in order to know each day whether or not the prothrombin is within

the desired limits and to determine when another dose of the drug should be given.

In doing the Quick prothrombin time test, thromboplastins of different potency, giving different normal prothrombin times and therefore different prothrombin times for certain degrees of prothrombin deficiency, are used in different hospitals and clinics. Also, unfortunately, thromboplastins may vary considerably in their potency even when prepared from similar sources and in the same way.⁹ For any type of thromboplastin which is used and when any new batch of thromboplastin is prepared, prothrombin times should be determined for 10 per cent, 20 per cent and 30 per cent dilutions of normal plasma. The results will be essentially the same if the dilutions are made with either prothrombin-free plasma or physiologic solution of sodium chloride. It is important that the physician who is supervising dicumarol therapy know each day the values in terms of prothrombin time in seconds for these three dilutions of normal plasma which can be considered as values for 10 per cent, 20 per cent and 30 per cent of normal prothrombin respectively.

What is the dose of dicumarol?—Dicumarol is effective when administered orally. A satisfactory preparation for parenteral use has not been developed. The following plan of dosage has been found to be simple and satisfactory and is recommended. All the dicumarol for one day is given in a single dose after the prothrombin time has been determined for that day. Three hundred milligrams are given the first day and 200 mg are given on each subsequent day that the prothrombin is greater than 20 per cent of normal. No dicumarol is given on days when the prothrombin is less than 20 per cent of normal. For the occasional patient who is found to be resistant to the drug the subsequent doses may be increased to 300 mg and if the patient is very sensitive to the drug, as indicated by rapidly developing and persistent severe prothrombin deficiency (below 10 per cent) after the usual doses, the dose may be reduced to 100 mg.

If dicumarol is given after a surgical operation for prophylaxis against thrombosis, administration is begun on the third postoperative day. When dicumarol is given to surgical patients prothrombin deficiency should be maintained until the patient leaves the hospital and for at least four days after he has been ambulatory. Daily prothrombin time tests should be done until the administration of the drug is discontinued. When dicumarol is given to nonsurgical patients the desirable duration of the prothrombin deficiency may be quite variable. If adequate protection against thrombosis and embolism is desired, the prothrombin deficiency should be maintained until the patient is ambulatory and in some instances for a considerably longer time. However, close observation of the patient and daily prothrombin time tests should be continued for the entire period.

Is dicumarol a dangerous drug?—The only untoward effect which has

been observed in human beings after dicumarol has been administered has been bleeding. If the contraindications to administration of dicumarol are observed and if the drug is administered according to the plan mentioned in the previous section the danger of bleeding is minimal. Minor epistaxis and microscopic hematuria may occur during administration of dicumarol but they may be disregarded. More serious bleeding may occur from recent operative wounds or ulcerative lesions, particularly of the gastro-intestinal tract. Usually such bleeding is not primarily caused by the prothrombin deficiency but what might have been minor transient bleeding becomes prolonged bleeding because of the prothrombin deficiency. Multiple widespread ecchymoses and hemorrhages are extremely rare. Definite bleeding is rare if the prothrombin does not fall below 10 per cent of normal and only occurs in about 4 per cent of cases when the prothrombin does fall below 10 per cent of normal. Among the first 1,000 patients who received dicumarol during the immediate postoperative period the incidence of serious bleeding was 2.5 per cent. Among the 318 patients who had had thrombophlebitis or pulmonary embolism it was only 1 per cent. Only one fatality from hemorrhage occurred among the 1,000 patients who received dicumarol during the postoperative period and in this case it is doubtful that the dicumarol was a factor, since there was relatively little prothrombin deficiency when bleeding occurred. The experience at the Clinic has been that, when properly used, dicumarol is no more dangerous than many other potent drugs.

How can excessive prothrombin deficiency or bleeding be controlled?—In using the plan of dosage recommended in this paper, patients may be encountered who have excessive prothrombin deficiency (below 10 per cent of normal) after the first one or two doses of the drug. Such patients usually are among the group who have recent or prolonged dietary deficiency or lesions of the gastro-intestinal tract and are usually those who have not had previous thrombosis or embolism. This excessive prothrombin deficiency can be restored to within safe limits in about 90 per cent of cases by a single intravenous injection of a large dose (60 mg.) of menadione bisulfite (2-methyl-naphthoquinone monosodium bisulfite).⁸ Thereafter dicumarol should be given more cautiously or in 100 mg. doses to that patient. If bleeding occurs during administration of dicumarol 60 mg. of menadione bisulfite should be given intravenously and the patient should be transfused with 500 c.c. of freshly drawn citrated blood, which will usually cause the bleeding to stop within a few hours. Rarely, subsequent transfusions and injections of menadione bisulfite may be necessary.

What are the deficiencies of dicumarol therapy?—As far as is known, dicumarol has no effect on a thrombus or embolus that is already present. It is used for the prevention of new thrombosis or extension of existing thrombosis and since emboli arise from fresh thrombi only, the prevention of fresh thrombosis will prevent embolism. The effect

of dicumarol is delayed for a day or more after it is administered and during this period the patient is not protected against thrombosis. The zone of effective and safe prothrombin deficiency produced by dicumarol is rather narrow (10 per cent to 30 per cent prothrombin) and the administration of dicumarol requires close observation of the patients and daily prothrombin time tests, therefore it is a rather unpractical method of preventing thrombosis for long periods (more than three months). Protection against thrombosis and therefore embolism ceases after the prothrombin deficiency induced by dicumarol ceases. There is the small risk of bleeding during the period of activity of the drug.

What is the best and simplest way to obtain a rapid anticoagulant antithrombotic effect and maintain it during a prolonged period?—Heparin injected intravenously will produce a rapid anticoagulant effect but it is impractical to use heparin for long periods because of its cost and the necessity for continuous or repeated intravenous administration. However, heparin can be administered during the few days between the time of administration of the first dose of dicumarol and the development of adequate prothrombin deficiency. The simplest method is to start the administration of heparin and dicumarol simultaneously giving 50 mg of heparin intravenously every four hours and giving the dicumarol according to the plan noted previously. As soon as the prothrombin is less than 20 per cent of normal the heparin may be discontinued. Prothrombin time tests to determine when this point is reached should be done at the end of the four-hour period after an injection of heparin and before the next dose of heparin is administered.

What are contraindications to the use of dicumarol?—Dicumarol is contraindicated in (1) the presence of definite renal insufficiency, because renal insufficiency greatly prolongs and increases its effect, (2) the presence of definite hepatic insufficiency for the same reason, (3) purpura of any type because of the danger of bleeding when capillary weakness and impaired coagulation are both present, (4) subacute bacterial endocarditis because of the vascular weakness caused by the disease and therefore increased liability to hemorrhage, (5) blood dyscrasia with tendency to bleed and (6) recent operation on the brain or spinal cord because of the grave consequence of even slight bleeding at the operative site. Dicumarol should be given cautiously to patients who have (1) ulcerative lesions, open wounds or potentially bleeding surfaces, (2) vomiting due to gastric or intestinal obstruction, (3) continuous or repeated gastric or intestinal drainage or (4) known dietary or nutritional deficiency. If patients are vomiting or have continuous or intermittent gastric or intestinal drainage by tube it may be futile to give dicumarol because the drug is absorbed poorly if at all.

What are the indications for the use of dicumarol?—Experience at the Clinic has indicated that the anticoagulant action of dicumarol is of

value in the following conditions (1) nonfatal postoperative, post-infectious or posttraumatic pulmonary embolism, because of the great risk of subsequent venous thrombosis and embolism during the subsequent few days or few weeks, (2) postoperative, postinfectious or posttraumatic thrombophlebitis because of the danger of extending or remote venous thrombosis and therefore of pulmonary embolism both fatal and nonfatal during the subsequent few days or few weeks, (3) after operations on patients who have previously had thrombophlebitis or pulmonary embolism because of the danger of recurrence of these complications, (4) after peripheral arterial embolism because of the danger of further intracardiac thrombosis and of propagating thrombosis from the embolus when the arterial spasm relaxes and (5) after acute peripheral arterial thrombosis from any cause because of the imminent danger of extending arterial thrombosis

Dicumarol may also be of value for patients who have thrombophlebitis or pulmonary embolism complicating blood dyscrasias or congestive heart failure, although there is a limit to the time that the anticoagulant effect can be maintained in these conditions and the thrombosing tendency may be prolonged. For the same reason dicumarol is of less value in recurrent idiopathic thrombophlebitis but during periods when the episodes recur with great frequency and may be interspersed with pulmonary infarcts, it may be advisable to use dicumarol. In postpartum thrombophlebitis or pulmonary embolism dicumarol should be used with caution although there is minimal risk of uterine bleeding if the uterus is normally involuted and if administration of the drug is not begun until the first postpartum week has elapsed.

In patients who have a large pulmonary embolism or acute peripheral arterial occlusion it is advisable to secure a rapid anticoagulant effect and to use preliminary heparinization as well as dicumarol. In cases of thrombophlebitis or in cases in which the drug is used for prophylactic purposes, preliminary heparinization is not necessary.

CLINICAL SIGNIFICANCE OF THE ERYTHROCYTE SEDIMENTATION RATE

DONALD R. NICHOLS

THE erythrocyte sedimentation test is being used rather extensively throughout this country as a routine diagnostic procedure. Its value as a routine procedure has been stressed by numerous investigators. Cutler⁴ reported that the test was of distinct diagnostic value in diseases characterized by disturbed stability of the blood. Schattenberg¹⁰ advocated the erythrocyte sedimentation rate as a routine test in life insurance examinations. Gallagher⁶ felt that the test could be used as a valuable part of health examinations of school children. Wintrobe¹² used the test as a routine procedure in the diagnostic clinic at Johns Hopkins Hospital. Agnor¹ reported the use of the test as a routine laboratory procedure in the Joseph H. Pratt Diagnostic Hospital. Reports by many other men from many other clinics have indicated that the test is being used widely in diagnostic centers and dispensaries and in the offices of individual physicians.

Helm⁸ recently has suggested that perhaps the sedimentation rate is being used too routinely in general medical practice. The value of the test in determining the prognosis and progress of disease has been questioned.³ There seems to be one point on which most investigators agree, however, namely, that the test is of definite value in indicating the presence of organic disease. Not infrequently, even before the disease can be recognized by the other usual clinical and laboratory methods, the presence of disease is suggested by an increased sedimentation rate.

The test is nonspecific and is of little value in distinguishing different diseases. It appears that the sedimentation rate varies with the amount of cellular destruction going on in the body.⁵ When the amount of destruction of tissue passes beyond the normal, the stability of the blood is seriously disturbed and the erythrocytes settle out quickly from the plasma. The preponderance of evidence indicates that there is a direct correlation between the concentration of fibrinogen in the plasma and the sedimentation rate of the erythrocytes. Serum globulin seems to have a definite effect, at times, and there is some evidence that the concentration of cholesterol in the plasma influences the sedimentation rate.⁷

The simplicity of the test is one of its greatest assets. The technique is very simple, no elaborate equipment is needed and the results are known within an hour. A modified Westergren method of determining the sedimentation rate is widely used.^{1, 2} The only special apparatus required is a Westergren tube and rack. It is also convenient to use a *e* with a mark indicating 5 c c. This may be a graduated centrifuge

tube or a plain test tube with a mark at the 5 c.c. level. The only reagent necessary is a 3.8 per cent solution of sodium citrate. The following technic is found to be satisfactory. Five-tenths cubic centimeter of a 3.8 per cent solution of sodium citrate in distilled water is placed in a tube, and to this is added 4.5 c.c. of venous blood. After the tube has been inverted several times to insure mixing, a Westergren tube is filled to the 200 mm. mark in a strictly vertical position at room temperature. The height of the column of plasma in the Westergren tube is read at the end of one hour and reported in terms of millimeters of sedimentation in one hour. In order that the test be accurate, certain factors must be emphasized. The tube must be absolutely vertical, the glassware must be clean, the test must be done within three hours after collection of the blood, and the temperature should be between 20° and 25° C.

With this method the normal sedimentation rate of men's erythrocytes is from 0 to 15 mm. in one hour, and the normal rate for healthy women is from 0 to 20 mm. Slightly elevated sedimentation rates are caused by so many factors that their significance is questionable. It is only when the sedimentation rate exceeds 30 mm. per hour that much importance can be attached to it.

When the sedimentation rate is used as a routine diagnostic test, certain problems arise in the interpretation of the results. A full consideration of all the diseases associated with an elevated sedimentation rate is beyond the scope of this paper. Fundamentally, any condition which produces significant destruction of tissue will cause an increased sedimentation rate,^{4, 8, 12} therefore, most acute and chronic infections, malignant lesions, acute intoxications and certain endocrine disturbances will be associated with an abnormal rate. A careful history and physical examination usually will reveal or suggest the cause for the elevated rate. Confirmatory laboratory tests may be necessary.

Not infrequently, however, a markedly elevated sedimentation rate will be found in a case in which there is no objective organic disease. The problem then is to determine, if possible, the cause for the elevation of the rate. The explanation may be found by means of other routine laboratory tests. It is the custom in most diagnostic clinics to do routine urinalyses and to make blood counts. Serologic tests for syphilis are also usually a routine procedure. If the sedimentation rate is being used as an office procedure and these tests have not been carried out, an erythrocyte count is the first procedure indicated, inasmuch as anemia will cause an increase in the sedimentation rate. A leukocyte count will indicate the presence of relatively severe infections or blood dyscrasias, urinalysis will disclose whether or not there is an infection of the urinary tract, and serologic tests for syphilis are indicated inasmuch as an elevated sedimentation rate will almost always be found when active syphilitic lesions are present.¹¹ Roentgenologic examination of the thorax certainly is indicated, as the sedimentation

tion rate has been shown to be a very sensitive indicator of active pulmonary tuberculosis and of nontuberculous processes in the lungs. Physical examination of the thorax often will fail to reveal these lesions. When the history, physical examination and the previously mentioned laboratory procedures fail to reveal any evidence of organic disease, the problem of accounting for the elevated sedimentation rate becomes definitely more difficult.

In one of the general medical sections at the Clinic, the sedimentation rate has been performed as a routine diagnostic procedure. Because of rather general agreement that an elevation of the sedimentation rate usually indicates the presence of disease, careful study has been given to those cases in which there is a high rate but in which the

TABLE 1—OBSCURE DISEASES OFTEN ASSOCIATED WITH AN ELEVATED SEDIMENTATION RATE

- I Generalized infection
 - A Atypical rheumatic fever
 - B Early rheumatoid spondylitis
 - C Fungous infection, such as abdominal actinomycosis
 - D Parasitic infection, such as malaria in the apyrexial stage
- II Localized infections
 - A Abscess of the liver
 - B Tuberculosis of bone
- III Malignant lesions

- IV Lymphoblastoma
- V Acute intoxications, such as lead poisoning
- VI Endocrine disorders, such as early Addison's disease
- VII Vascular occlusion or inflammation, such as a mild, rather silent type of coronary occlusion
- VIII Diseases of the liver, such as cirrhosis

results of physical examination and routine laboratory tests are essentially negative. The routine laboratory tests which customarily are made include a leukocyte count, erythrocyte count, hemoglobin determination, urinalysis, flocculation test for syphilis, and a roentgenologic examination of the thorax. The history often is helpful in establishing the diagnosis. At other times, however, even the history is non-contributory.

In interpreting the significance of a markedly elevated sedimentation rate it must be remembered that the sedimentation rate returns to normal only very slowly. Moen and Reimann⁹ have pointed out that normal rates usually are not obtained before one to two months after the acute phase of pneumonia. Ham and Curtis have shown that a single injection of typhoid vaccine will cause elevation of the rate as long as ten days. Markedly elevated rates will often be found

two months after clinical recovery from severe septicemia. Therefore, elevated sedimentation rates are of no significance in cases in which the patients have had a severe acute infection in the preceding weeks. Furthermore, when an elevated sedimentation rate is found, the test should be repeated after a period of time. This will serve as a safeguard against laboratory errors. Moreover, much more importance should be given to a sedimentation rate which is increasing or which remains markedly elevated than to one which is steadily approaching normal.

Table 1 lists some of the rather obscure diseases which may cause a marked elevation of the sedimentation rate. In this group of diseases the results of physical examination and routine laboratory tests may be negative and the history may not be diagnostic. The sedimentation rate may be markedly elevated.

There are undoubtedly many other diseases which could be added to this table. However, this classification will serve as a guide to some of the obscure or occult diseases which are often associated with an elevated sedimentation rate.

REPORT OF CASES

I shall report two cases which illustrate the value of the sedimentation rate as a routine procedure and the attention which must be paid to an elevated sedimentation rate.

CASE 1.—The patient was a white man forty nine years of age. He was first seen at the Clinic on March 26, 1942. His chief complaints were of chronic fatigue and recurrent episodes of severe dizziness. He had had no episodes of true vertigo. The results of physical examination, including a complete neurologic examination, were essentially negative, except for a mild chronic prostatitis. The blood pressure was 110 mm. of mercury systolic and 70 mm. diastolic. The value for the hemoglobin was 13.1 gm per 100 c.c. of blood. The erythrocyte count was 4,620,000. The leukocyte count was 8,400 and the differential count was normal. A flocculation test for syphilis was negative. Urinalysis did not reveal any abnormality. Roentgenograms of the thorax revealed calcification of the pleura at the base of the right lung but were otherwise normal. A roentgenogram of the head was normal. The sedimentation rate determined by the Westergren method was 60 mm at the end of one hour.

In view of the negative results of physical examination and laboratory tests, the symptoms would have been considered functional in nature if it had not been for the high sedimentation rate. He was therefore kept under observation and typical Addison's disease developed subsequently.

CASE 2.—The patient was a white man fifty-seven years of age. He was first seen at the Clinic in April 1942. He gave a history of recurrent attacks of low back pain. There had been no sciatic extension of the pain and coughing had not aggravated the distress. Changes in the weather had no effect, and there was no stiffness noted on arising. The results of physical examination were essentially negative. Motions of the back were normal. The leukocyte count was 5,300 and the value for the hemoglobin 13.1 gm per 100 c.c. of blood. Urinalysis did not reveal any abnormality. Roentgenologic examination revealed narrowing of the

fourth and fifth lumbar interspaces, but otherwise did not disclose any abnormality. The value for the blood urea was 30 mg per 100 c c. The value for the serum phosphatase was 12 Bodansky units. The sedimentation rate determined by the Westergren method was 59 mm in one hour on one occasion and 67 mm on another.

The patient was suspected of having a protruded intervertebral disk, but there was little objective evidence for such a diagnosis. The high sedimentation rate indicated the presence of some active disease. However, there was no evidence of a spondylitis. In spite of extensive investigation, a definite diagnosis could not be reached, and it was felt that the patient should be kept under observation. Subsequent examinations later revealed the presence of multiple myeloma. This man's trouble would have been considered purely mechanical in nature if the markedly elevated sedimentation rate had not been found.

COMMENT

In both of these cases the sedimentation rate played a very significant role in indicating the presence of disease, although the results of physical examination and other laboratory tests were negative.

As stated previously, certain laboratory procedures are indicated when a high sedimentation rate is encountered and the disease is obscure. A leukocyte count, an erythrocyte count, a urinalysis, a flocculation test for syphilis and a roentgenologic examination of the thorax are essential. If the results of these tests are negative, certain other laboratory tests may at times be of value.

Determination of the concentration of serum protein often will reveal some gross abnormality in the protein metabolism and will serve as a lead to the diagnosis. For example, an excessively high concentration of serum globulin is suggestive of multiple myeloma.

Determination of the alkaline and acid phosphatase level in the blood occasionally will indicate the presence of a metastatic malignant lesion.

A liver function test may at times be indicated, inasmuch as cirrhosis of the liver or metastatic lesions in the liver occasionally cause a markedly elevated sedimentation rate.

Examination of special blood smears often will give information which is very helpful in establishing the diagnosis of an obscure disease.

Electrocardiographic findings in the presence of an elevated sedimentation rate occasionally will establish the diagnosis of coronary occlusion when the history is not diagnostic.

Even in spite of careful study, there will be an occasional case in which no adequate explanation for the increased sedimentation rate can be found. In such instances, the physician must rely on his clinical judgment and not become confused by the results of a single laboratory test. However, it should be remembered that repeated studies have consistently shown that an elevated sedimentation rate is usually a sign of the presence of organic disease. Therefore, when possible, it is wise to keep in touch with a patient who has an elevated sedimentation rate but no other evidence of organic disease, until the rate has

returned to normal or the cause for the elevation of the rate has become apparent.

SUMMARY

The erythrocyte sedimentation rate is a simple test which can be used effectively as a routine diagnostic procedure in office practice as well as in large clinics. Its greatest value when it is used as a routine procedure is that it may call attention to obscure or occult diseases before these diseases can be recognized by the usual clinical and laboratory methods. A complete history, physical examination and certain other laboratory tests are indicated in those cases in which a high sedimentation rate is found and in which no specific disease is evident.

THE DIAGNOSIS OF RAYNAUD'S DISEASE

EDGAR A. HINES, JR

It is well recognized that symptoms and signs of disturbance of the peripheral circulation may occur in the absence of any demonstrable organic disease of the vascular system. Such disturbances have been thought to be on a functional basis and frequently have been considered as functional vascular disease. One form of functional vascular disease is that in which spasm of the arteries or arterioles produces changes in color of the skin. In some instances the arterial spasm is severe enough to produce marked pallor and even the waxy color of the so-called dead finger. In other instances the changes in the peripheral circulation are of such degree that only a bluish (cyanotic) discoloration results. It has long been known that even moderate exposure to cold or an emotional upset would produce vasospasm with color changes in the skin of the extremities of certain persons.

Raynaud first emphasized that functional disturbances in the peripheral circulation at times may become severe and that they occasionally result in changes in the integrity of the skin and even in symmetrical gangrene. He noted that changes in color of the skin of the extremities indicative of disturbances in circulation could occur in the absence of any evidence of occlusive arterial disease. He was not aware, however, that these vasospastic changes also could be induced by certain occlusive arterial diseases and that they might occur in many other conditions involving organic disease of the blood vessels, the nervous system or skin. Following Raynaud's description, many of the conditions associated with color changes in the skin of the extremities, including symmetrical gangrene of the members, were termed "Raynaud's disease." Hutchinson was the first to recognize clearly that Raynaud had not described a separate entity when he described the intermittent color changes occurring on exposure to cold and the symmetrical gangrene which sometimes was observed in association with these intermittent color changes. Hutchinson wrote, "all who have studied in any detail the cases which have been grouped together under the name of Raynaud's disease will admit that the time has arrived when they ought to be classified. They are not all alike nor do they all tend to the same result. It would be well indeed if we could cease to use the term Raynaud's disease and speak rather of Raynaud's phenomenon. The latter expression is capable of having assigned to it a clear and definite meaning, the former is not. The phenomena in question are those of acroteric asphyxia and are liable to variation at different times, being in many cases distinctly paroxysmal and are to be explained by reference to the influence of the nervous system upon the blood vessels. Many of the cases which

have been quoted as examples of Raynaud's disease are, however, complicated or even primarily induced by organic disease of the skin (scleroderma), the blood vessels or the heart "

Hutchinson, besides suggesting use of the term 'Raynaud's phenomenon' to connote the episodes of color change in the extremities, recommended the use of further terms to indicate the underlying cause of the phenomenon, for example "traumatic Raynaud's phenomenon."

By "Raynaud's phenomenon" is meant the occurrence of *intermittent* episodes due to a vascular disturbance either primary or secondary, resulting in color changes of the extremities, principally the fingers and toes and less frequently the hands, feet, nose and ears initiated by exposure to cold and less frequently by emotional or nervous strain and stress

In a small group of cases in which Raynaud's phenomena are present, however, it is impossible to demonstrate, even after the lapse of several years, any occlusive arterial disease or, in fact, any cause for the functional vascular changes. To this group the term "Raynaud's disease" may still be applied

CLINICAL DESCRIPTION

The typical history in Raynaud's disease is that of a young woman who first observed color changes of the type of Raynaud's phenomenon on exposure to cold. Usually the onset of such alterations in color is not striking, although in some instances they may be called dramatically to the patient's attention by an acute episode of pallor in one or two fingers on exposure to cold, the so called dead finger phenomenon. In the early stage of the disease, only the tips of the fingers of both hands are involved. Later, the changes in color of the skin involve more of the proximal parts of the fingers until, in the late stages, the modifications in color may extend back to involve the hands. The color changes may consist of cyanosis solely or pallor solely but more commonly the variation in color is in three phases pallor, cyanosis and rubor. Symptoms are worse in the cold season and better in the warm season. Pain is not a prominent symptom during the attack or in the interval between attacks. Paresthesia, however, does occur commonly during the attack and consists of numbness, tingling, burning, a feeling of tightness, a "pins and needles" sensation or a sucking sensation in the fingers. During the attack, the fingers are cold and in many instances there is actual diminution of sensory acuity. In some cases slight swelling of the involved fingers may occur and, in others, the swelling may persist even during the interval between the attacks

In the progressive or advanced stages of Raynaud's disease the Raynaud's phenomenon may become disabling in its severity and frequency. The attacks may occur on exposure to a slightly cool environment and under almost any emotional stress, consequently even the

warmer weather of the summer season may afford little relief. In many instances, sclerodermatous changes of considerable degree may affect the skin of the involved parts and may result in considerable interference with the normal use of the extremity, particularly of the fingers. Although extensive gangrene does not occur, the gangrenous ulcerations on the tips of the digits may be persistent and may cause considerable pain and discomfort. In an occasional instance these lesions may become infected and it may be necessary to amputate the distal parts of the involved finger or fingers. I have never seen a lesion in Raynaud's disease necessitating the amputation of a toe or of more than a portion of a finger.

DIAGNOSIS

If the term "Raynaud's disease" is to be continued in use, strict adherence to accepted criteria for diagnosis must be observed. The medical literature is greatly confused by many cases in which an incorrect diagnosis of Raynaud's disease has been made. Since it has become more widely recognized that symmetrical gangrene does not occur solely, or even usually, in Raynaud's disease, mistakes in the diagnosis of Raynaud's disease have become fewer.

Identification is relatively easy if the diagnosis of Raynaud's disease is made only in cases in which Raynaud's phenomenon occurs without evidence of secondary cause and in which it is bilateral. It should have existed long enough in each case for any secondary cause to have become evident before a final diagnosis of Raynaud's disease is made.

The criteria for making a diagnosis of Raynaud's disease may be summarized briefly as follows: (1) episodes of Raynaud's phenomenon excited by cold or emotion, (2) bilaterality of the Raynaud's phenomenon, (3) absence of gangrene or, if present, its limitation to minimal grades of cutaneous gangrene, (4) absence of any other primary disease which might be causal, such as occlusive arterial disease, cervical rib or organic disease of the nervous system and (5) history of symptoms being noticed for two years or longer.

The most important point in making the diagnosis is the elimination of any possible secondary factors which within reason may be the cause of Raynaud's phenomenon. It should be remembered that secondary Raynaud's phenomenon is much more common than Raynaud's disease.

DIFFERENTIAL DIAGNOSIS

In making the differential diagnosis, inquiry should be made as to possible contact with heavy metals and ergot. The family history of similar disturbances affecting other members of the family also may be helpful. When Raynaud's phenomenon has been restricted to one finger or to one extremity for a long period, some secondary causative factor should be suspected. When Raynaud's phenomenon occurs

in a man, it should be suspected of being due to thrombo-angitis obliterans or to some other organic factor

In making a differential diagnosis of Raynaud's disease from other diseases the prime objective is to rule out occlusive arterial disease

Thrombo-angiitis Obliterans (Table 1)—A review of the literature of vascular disease soon indicates that the disease which is most commonly confused with Raynaud's disease is thrombo-angitis obliterans. Three reasons are mainly responsible: 1. The emphasis which Raynaud gave to the symptom of symmetric gangrene resulted in confusion in diagnosis and many cases in which some degree of occlusive arterial disease, usually thrombo-angitis obliterans, was present were considered to

TABLE —DIFFERENTIAL DIAGNOSIS OF RAYNAUD'S DISEASE, THROMBO-ANGIITIS OBLITERANS AND ARTERIOSCLEROSIS OBLITERANS

	Raynaud's Disease	Thrombo-angiitis Obliterans	Arteriosclerosis Obliterans
Sex	Females in 70 per cent of cases	Males in 98 per cent of cases	Males in 85 per cent of cases
Age of onset years	12 to 30	20 to 40	More than 50
Color changes Raynaud's phenomenon Postural color change	100 per cent of cases Absent	30 per cent of cases 100 per cent of cases	10 per cent of cases 100 per cent of cases
Gangrene (if present)	Limited to small areas of skin	Minimal to extensive	Minimal to extensive
Involvement of upper extremities	Almost all cases	40 per cent of cases	Rare
Involvement of lower extremities	Usual but less frequently than upper extremities	98 per cent of cases	100 per cent of cases
Symmetry	Bilateral and symmetrical	Asymmetrical but usually bilateral	Asymmetrical but usually bilateral
Peripheral arterial pulsations	Present	Impaired or absent	Impaired or absent
Calcified arteries	Absent	Usually absent	Usually present
Superficial phlebitis	Absent	40 per cent of cases	Absent
Acrosceleroderma	None or moderate	Absent	Absent

have been cases of Raynaud's disease in subsequent descriptions. 2. Raynaud's phenomenon often occurs in both the upper and lower extremities in the early stages of thrombo-angitis obliterans. 3. The symptoms of Raynaud's disease and of thrombo-angitis obliterans usually begin in early adult life.

The differential diagnosis between these two conditions is not unusually difficult. The difference in sex incidence alone should indicate the differential diagnosis in the majority of cases inasmuch as Raynaud's disease occurs largely among females and thrombo-angitis obliterans, largely among males. In thrombo-angitis obliterans one extremity is usually involved first, whereas in Raynaud's disease both

upper extremities are usually involved first Raynaud's phenomenon when present in association with thrombo-angitis obliterans, is likely to involve only one or two digits even in the late stages of the disease A history of recurring superficial phlebitis also should arouse suspicion of thrombo-angitis obliterans as this does not occur in Raynaud's disease The final diagnosis of thrombo-angitis obliterans can be made by the demonstration of permanent arterial occlusion which, if present, rules out the possibility that the patient under consideration has Raynaud's disease In an occasional case, particularly in cases of thrombo-angitis obliterans in which only the digital arteries are involved, an arteriogram is necessary in order to demonstrate the presence or absence of occlusive arterial disease

Arteriosclerosis Obliterans (Table 1) —Raynaud's phenomenon rarely occurs in its typical form in arteriosclerosis obliterans and, when it does occur, usually only one or two digits are involved and usually pallor is an outstanding feature, with cyanosis being minimal or absent Age and sex are of great significance in consideration of a diagnosis of arteriosclerosis obliterans Raynaud's disease rarely begins in persons within the age limit in which arteriosclerosis obliterans occurs, namely, after fifty years of age Evidence of arteriosclerosis, of signs of other senile changes and of occlusive arterial disease, of course, will immediately point to a diagnosis of arteriosclerosis obliterans As in thrombo-angitis obliterans, the lower extremities are first and more extensively involved in arteriosclerosis obliterans, contrary to the involvement which occurs in Raynaud's disease In an occasional instance estimations of the fat in the blood are of value in differential diagnosis In arteriosclerosis obliterans the blood lipoids in many instances will be found to be elevated markedly whereas they are almost never markedly elevated in uncomplicated Raynaud's disease

Acrocyanosis (Table 2) —The sex and age of patients who have acrocyanosis and Raynaud's disease are similar Both diseases usually attack young women In acrocyanosis, however, the episodic nature of the color changes is not nearly so striking as it is in Raynaud's disease In acrocyanosis, the changes in color of the skin consist mostly in cyanosis which is of a diffuse nature and is more permanent than in Raynaud's disease Although the color changes in acrocyanosis may be increased by cold, there is often little effect from heat and vasodilatation Necrosis and ulceration of the finger tips sometimes occur in the late stages of Raynaud's disease, whereas such changes almost never occur in acrocyanosis

Livedo Reticularis and Chronic Pernio (Table 2) —Livedo reticularis easily is distinguished from Raynaud's disease by the *permanent*, reticulated pattern of the color changes These color changes usually involve all four extremities and sometimes the trunk, whereas, in Raynaud's disease, usually only the hands and feet are involved

Chronic pernio, a form of chilblains, is distinguished by the appearance, about and above the ankles, of typical, superficial skin lesions

TABLE 2 —DIFFERENTIAL DIAGNOSIS OF RAYNAUD'S DISEASE, ACROCYANOSIS, LIVEDO RETICULARIS, PERNIO AND ACROSCLEDERMIA

	Raynaud's Disease	Acrocyanosis	Livedo Reticularis	Pernio (erythrocyanosis)	Primary Scleroderma
Sex and age	Girls or young women in 70 per cent of cases	Girls or young women in 90 per cent of cases	Women or men, any age	Young women 70 per cent of cases	Young women 85 per cent of cases
Type of color change	Blue, red, white mottled or diffuse	Blue, diffuse	Red blue, mottled and reticulated	Blue, red, localized	Blue, red, white mottled or diffuse
Location of vascular symptoms	Hands, feet nose and ears rarely	Hands usually feet occasionally	Less usually arms occasionally	Exposed surfaces, legs especially	Hands and feet
Duration of vascular symptoms	Intermittent	Permanent	Permanent	Variable worse in winter	Intermittent
Local symptoms	Numb or burning pain	None	None	Marked itching and burning	Stiffening and tenderness of skin
Effect of cold	Symptoms increased	Symptoms increased	Increased blueness	Causal increased redness	Symptoms increased
Effect of heat and vasodilatation	May decrease color changes greatly	Little change	Less blueness	More redness	May be decreased color changes
Effect of posture and exercise	Little change	Cyanosis decreased on elevation	Cyanosis decreased by elevation or exercise	No change	No change
Swelling	Slight or none	Slight or none	Slight or none	Slight or none	Slight to moderate
Necrosis and ulceration	Slight or limited or none	None	Occasionally in severe cases	Always in severe cases	Frequently in association with marked scleroderma

which appear in the cool seasons and disappear during the warm seasons. The patient suffering from chronic pernio may also have cold, cyanotic feet and hands, but, in the uncomplicated case, Raynaud's phenomenon does not occur.

Acroscleroderma (Table 2) —There is seldom any difficulty in distinguishing between the late stages of primary scleroderma and Raynaud's disease. However, in the early stages of primary scleroderma there may be considerable difficulty in determining whether the condition is the condition just named or Raynaud's disease. In attempting to establish the difference it is important to determine whether the Raynaud's phenomenon began before or after the onset of noticeable changes in the skin or periarticular tissues. If the Raynaud's phenomenon occurred before any changes in the skin were noted and if it has persisted for months or several years with only minimal sclerodermatous changes, then it is likely that Raynaud's disease is present. In the later stages of primary scleroderma the sclerotic changes involve the skin of the arms, face, chest and neck, these regions are not involved in the color changes. In Raynaud's disease, however, the changes in the skin occur only in or near the sites at which the color changes have been most marked, usually in the ends of the fingers or toes.

THE EFFECT OF SMOKING CIGARETS AND THE INTRA VENOUS ADMINISTRATION OF NICOTINE ON THE HEART AND PERIPHERAL BLOOD VESSELS

GRACE M ROTH, JOHN B McDONALD* AND CHARLES SHEARD

PERHAPS there is no more controversial subject today than the effects of smoking tobacco on the heart and peripheral blood vessels. There are many excellent papers on this subject but, in spite of all the comprehensive work, complete agreement among the various investigators is still lacking. For the most part this subject has been concerned with three major controversies: (1) whether the smoking of tobacco is an etiologic factor in organic circulatory disease, (2) whether vasoconstriction of the peripheral blood vessels takes place and to what degree as the result of smoking of tobacco, and (3) whether the effect is produced by the cigaret paper, the tobacco smoke, the nicotine or the mechanical act of smoking. In regard to the first controversy, experimental, clinical and statistical evidence has shown that smoking of tobacco most likely is only a contributory factor and not the exciting one.

The existence of vasoconstriction of the peripheral blood vessels may be determined by an increase in blood pressure and pulse rate, by a decrease of the cutaneous temperatures of the extremities or by a decrease of the velocity of blood flow of the peripheral vessels of the extremities as measured by the plethysmograph. Most investigators have agreed that an elevation of blood pressure and pulse rate occurs during smoking of tobacco. Definite vasoconstriction of the peripheral blood vessels as evidenced by a decrease of the cutaneous temperature of the extremities has been reported by Maddock and Coler,⁹ Barker,¹ Wright and Moffat¹⁵ and Lampson⁸ and Moyer and Maddock.¹¹ With the exception of Mulinos and Shulman¹² the investigators generally have reported that smoking of tobacco causes a decrease of peripheral blood flow as measured by the plethysmograph. Mulinos and Shulman attributed the decrease in blood flow to deep breathing. Similarly Smithwick¹³ reported a decrease in blood flow through the finger by immersion of the contralateral hand in cold water, by a loud noise or even by an unpleasant thought.

In regard to the precipitating factor which produces the vasoconstriction, Barker¹ in 1933 presented evidence that the effect of smoking on the peripheral blood vessels was due to the absorbed portion of the tobacco smoke and not to the cigaret paper. Other investigators have shown that the substances contained in tobacco smoke absorbed by the

Dr McDonald is Captain, Medical Corps, Army of the United States. Work done as a student officer while on assignment at the Mayo Foundation for instruction in internal medicine.

body are pyridine bases, carbon monoxide and nicotine. The pyridine compounds are irritating to the mucous surface and for the most part the amounts absorbed are too small to be of physiologic interest. Other investigators have found that the average saturation of carbon monoxide in the blood of smokers who inhaled was about 5 per cent in contrast to the 15 to 20 per cent saturation necessary to cause disagreeable symptoms in normal individuals. Maddock and Collier¹⁰ and Moyer and Maddock presented evidence that the vasoconstriction produced by smoking standard cigarettes was analogous to that produced by the intravenous injection of a similar amount of nicotine contained in the standard cigarette. Furthermore, they, as well as Wright and others, noted that smoking cigarettes which did not contain nicotine produced no appreciable effects on the cutaneous temperature of the extremities. Goetz⁴ in 1942 reported that the decrease in peripheral blood flow was first the result of reflexes due to the irritating effect of the smoke upon the mucosa of the lung and later due to the nicotine absorbed and accumulated during smoking. Haag⁵ further supported the evidence of the role of nicotine when he demonstrated in animals that the rises of blood pressure occasioned by the intravenous injection of smoke solutions were proportional to their nicotine content.

In 1943, three interesting papers on smoking appeared. Johnston⁷ in England added support to the nicotine theory in that he assumed that smoking of tobacco is essentially a means of administering nicotine. He felt that smokers showed the same attitude toward tobacco as addicts to a particular drug. He gave nicotine both hypodermically and intravenously and derived the same response as from the inhalation of tobacco smoke.

Weatherby¹⁴ found that vasoconstriction took place after smoking standard cigarettes and when nicotine was removed from standard cigarettes and the denicotinized cigarettes were smoked the vasoconstriction was abolished almost completely. Restoration of the original nicotine content to such cigarettes restored the original effects, indicating that nicotine is the most important agent which contributes to the circulatory and cutaneous changes and not the altered respiratory movements associated with smoking, as suggested by Mulinos and Shulman. He also noted that when the subjects were ambulatory, vasoconstriction of the peripheral blood vessels did not occur during the smoking of standard cigarettes.

In contrast, Evans and Stewart² found a similar decrease in peripheral blood flow with reduction of the cutaneous temperature of the extremities as a result of smoking standard cigarettes, denicotinized cigarettes or cigarettes not containing any nicotine (corn silk). They attributed these changes to sympathetic stimulation brought about by the irritating effect of smoke upon the respiratory tract, and not to the nicotine content of the cigarettes. Thus the third controversy still exists. In addition, some investigators felt that habitual smokers devel-

oped a tolerance to tobacco and had little, if any, physiologic response to smoking

PROCEDURE

Observations were made on four male physicians and two female technicians whose ages ranged from twenty-two to forty-one years. All were habitual smokers and inhaled during smoking. As they were accustomed to the procedure in the psychrometric room psychologic stimulation was at a minimum.

Standard cigarettes of different brands bought on the open market were used. As a control, cigarettes made of corn silk were smoked. Comparative studies with standard cigarette paper and French ashless cigarette paper were used with both standard cigarette tobacco (1 gm.) and corn silk to investigate the possibility of an irritating factor in the preparation or bleaching process of the paper. A popular British cigarette filter holder also was used with the standard cigarettes.

Data were obtained in a constant temperature room with an environmental temperature of 78° F (25.5° C.), with a relative humidity of 40 per cent. The subjects fasted for fifteen hours previous to the test, during the test they wore lightweight short pajamas and were in the supine position on comfortable beds.

The temperatures of the plantar surface of the first and third toes of both feet and the volar side of the distal phalanges of the first and third fingers of both hands were measured by means of copper-constantin thermocouples. In many instances mouth temperatures were noted before and after smoking and in several instances rectal temperatures were recorded simultaneously with those of the fingers and toes. When fairly constant readings of the cutaneous temperatures had been obtained and after the basal blood pressure and pulse rate had been determined, smoking was begun. Simultaneous determinations of the blood pressure, pulse rate and cutaneous temperature were obtained at intervals of one minute during the smoking period, which generally lasted about twelve to sixteen minutes. The subjects inhaled the tobacco smoke with their accustomed depth and frequency. The observations were continued for thirty minutes to one hour after smoking was discontinued. An attempt was made to avoid all unnecessary noise and other stimuli which might produce vasoconstriction during this period. In addition, a cold pressor test was done on each subject.

RESULTS

Sixty-six observations were made on six normal subjects who were inveterate smokers and all of them inhaled. Unless otherwise stated the cutaneous temperature was measured while the subjects were resting in the supine position wearing lightweight short pajamas. When an unlighted cigarette was puffed for the period it usually took to smoke two standard cigarettes, there was little or no change of the cutaneous temperature of the extremities, of blood pressure or of the pulse rate.

Fig 144—Effect of puffing on an unlighted cigaret, smoking two corn silk cigarets and smoking two standard cigarets on the cutaneous temperature of the extremities, blood pressure and pulse rate of the same subject. The cutaneous temperature curves of only one toe and one finger are shown. The control period in each instance was thirty minutes (Authors' article in J A M A, Vol 125,

Fig 145—Effect of smoking two standard cigarets on the cutaneous temperature of the extremities the blood pressure and the pulse rate of the same subject while sitting and during slow walking. Note the decrease of the cutaneous temperature (Authors' article in J A M A, Vol 125)

(fig 144) This was in accord with the findings of Evans and Stewart. When two corn silk cigarettes were smoked, there was a decrease of the cutaneous temperature in only two instances of 0.1° to 0.7° C. in the toes with a decrease of 0.6° to 2.0° in the fingers, and the blood pressure and pulse rate were practically unchanged (fig 144). The effect of smoking corn silk cigarettes was not irritating as evidenced by the absence of nasopharyngeal irritation and coughing. When two standard cigarettes were smoked there was an average decrease in the skin

Fig 146.—Effect of smoking two standard cigarettes on the cutaneous temperature of the extremities, the blood pressure and the pulse rate of 3 normal subjects characterized by three different basal metabolic rates. When the basal metabolic rate is low the cutaneous temperature of the toes is correspondingly low when the basal metabolic rate is high the cutaneous temperature of the toes is high (Authors article in JAMA, Vol 125)

temperatures of the toes of 1.8° C. with a range of 0.7° C. to 4.3° C. while in the fingers the average decrease was 3.2° C. with a range from 1.2° to 6.5° C. The greatest decrease in any one digit was 4.3° C. for the toes and 7.7° C. for the fingers.

When French ashless cigarette papers were used with the amount of tobacco in a standard cigarette or with corn silk, the effect on the cutaneous temperatures of the extremities, blood pressure and pulse rate corresponded to the effect produced by the respective cigarettes alone. The British filter holder together with standard cigarettes produced the same decrease in cutaneous temperature of the extremities

and the same increase of blood pressure and pulse rate as did the standard cigarettes alone

Since the criticism has been made that not many individuals smoked while in the supine position in bed, observations were made when the subject was fully clothed and in a sitting position and during slow walking. The thermocouples were placed inside the socks and shoes. Observations were first made during a thirty minute control period, then during the period when two standard cigarettes were smoked (fig 145). The decrease in the cutaneous temperature of the extremities was similar to that found under basal conditions and these results were contrary to those of Weatherby.

Fig 147—Electrocardiographic tracings taken on the same subject on different days. In the tracings the heart rate is the same before smoking, after smoking corn silk and while physiologic salt solution was being administered intravenously, and the amplitude of the T waves does not vary more than from 0.5 to 1.0 mm. The heart rate after the subject had smoked two standard cigarettes was 100 beats per minute, while the subject was receiving nicotine intravenously the rate was 110 beats per minute. The amplitude of the T waves decreased about 1 mm more as the result of intravenous administration of nicotine than during the smoking of two standard cigarettes. There was a definite decrease both from smoking two standard cigarettes and from the intravenous administration of nicotine, averaging between 1 and 3 mm (Authors' article in JAMA, Vol 125).

As has been previously shown, there is a more or less linear relationship between the skin temperature of the toes and the basal metabolic rate. When two standard cigarettes were smoked, the decrease in the skin temperature of the toes was partially dependent upon whether the basal metabolic rate was low or high. The different decreases in the skin temperature of the toes and the fingers with various basal metabolic rates are shown in figure 146. Furthermore, the basal metabolic rate increased with the smoking of two standard cigarettes and decreased with the smoking of two corn silk cigarettes by the particular subjects. These results are similar to those of Goddard and Voss³ and Evans and Stewart, who found an increase in 69 per cent of their subjects.

The electrocardiographic tracing made before smoking in one case is shown in figure 147. All tracings made after smoking standard cigarettes had resulted in an increase of heart rate averaging between 16 and 36 beats per minute. A decrease in the amplitude of the T waves was noted in all subjects. The average decrease was between 1 and 2 mm in all leads and in a few instances the T wave in lead III became iso-electric. The greatest decrease in amplitude of the T waves was noted after the smoking of standard cigarettes. The tracings made after smoking corn silk showed no changes in amplitude of the T waves, the maximal decrease in amplitude of the T waves ranged be-

Fig 148—Effect of smoking two corn silk cigarettes, of smoking two standard cigarettes and of an intravenous injection of 2 mg of nicotine on the cutaneous temperature of the extremities, the blood pressure and the pulse rate of the same person. (Authors' article in J.A.M.A., Vol 125)

tween 0.5 and 1.0 mm, and in three instances there was a slight increase in amplitude of the T waves. Changes in amplitude of the QRS were negligible and in no instance was there an increase in the PR or the QRS intervals. Physiologic salt solution and nicotine also were administered intravenously. After basal tracings had been made an infusion of isotonic solution of sodium chloride was started. When basal tracings had been made under these circumstances without the patients being aware of the change, 2 mg of nicotine was given through the same apparatus. The electrocardiographic tracings made during the administration of physiologic salt solution resulted in no increase in

The electrocardiographic tracings made during the administration of physiologic salt solution resulted in no increase in

the heart rate and in one instance in a decrease in the heart rate. There was either no change in the amplitude of the T wave or a maximal decrease of between 0.5 and 1.0 mm. After the intravenous administration of nicotine the tracings showed an average increase of heart rate of between 30 and 40 beats per minute. In all subjects there was an average decrease in amplitude of the T waves of between 1 and 3 mm in all leads and in a few instances the T waves demonstrated negativity in lead III. Changes in amplitude of the QRS were negligible and in no instance was there an increase in PR or the QRS intervals.

A comparison of the results of smoking corn silk cigarettes, smoking two standard cigarettes and an intravenous administration of nicotine was made on the same individual (fig. 148). With intravenous administration of physiologic salt solution for fifteen minutes previous to the injection of nicotine there was a slight decrease in the skin temperature of the extremities in two of the subjects. After the administration of 2 mg. of nicotine there was a sharp decrease in the skin temperature of the extremities in all subjects, at least parallel to that produced by two standard cigarettes.

While Hines and one of us (G. M. R.⁶) found an excessive rise of the blood pressure in patients with hypertension during smoking, in some normal individuals there may be a parallelism between hyper-reaction to the cold pressor test and hypersensitiveness to tobacco, in many other individuals hyper-reaction may be due to one or the other cause.

SUMMARY

This investigation was begun primarily to determine whether habitual smokers with normal blood pressure and pulse rate and normal vascular systems develop a tolerance to tobacco or demonstrate any physiologic changes as a result of smoking. Vasoconstriction in these subjects was evidenced by a decrease in the skin temperature of the extremities and an increase in blood pressure and pulse rate during smoking of two standard cigarettes. An increase in the basal metabolic rate and changes in the electrocardiographic tracings also took place. The blood pressure, pulse rate and electrocardiographic tracing was normal within five to fifteen minutes after the smoking ceased, while the peripheral vascular constriction, as evidenced by a decrease in skin temperature, persisted from a half to one hour. There was some variation in the degree of response to smoking in different individuals and in the same subject from day to day.

While most individuals smoke when sitting or walking, few observations have been made under these circumstances. Weatherby reported that mild physical activity inhibited the fall in skin temperatures of the extremities when smoking one cigarette. However, we found the same degree of vasoconstriction in our subjects who were fully clothed during the smoking of two cigarettes while sitting or walking slowly as when they were at rest under basal conditions.

Since vasoconstriction was not evident during the puffing of an unlighted cigaret, and during the smoking of corn silk cigarettes, the mechanical effort of smoking was not a factor in the production of vasoconstriction. As Barker had previously stated, we found that various cigaret papers were not a factor in the production of vasoconstriction. This leaves the absorbed products of the tobacco to be accounted for. We had the opportunity of observing the effects of nicotine alone. We confirmed the observation of Maddock and Collier and Moyer and Maddock in regard to the peripheral vasoconstriction as evidenced by the decrease in skin temperatures and an elevation of blood pressure and pulse rate produced by both smoking of standard cigarettes and by a similar amount of nicotine injected intravenously. In addition, we compared for the first time the effect of smoking standard cigarettes and the intravenous injection of a similar amount of nicotine on the electrocardiographic tracings of the subjects and found them strikingly similar.

IRON DEFICIENCY AND ANEMIA ASSOCIATED WITH CARCINOMA OF THE PROXIMAL PORTION OF THE COLON*

R LEE CLARK, JR.,† MARSCHELLE H POWER, FRANK J HECK AND
CLAUDE F DIXON

THE majority of opinions regarding anemia associated with carcinoma of the right portion of the colon have been based on the study of specimens long after they have been removed and stored in fixing solutions and after the histories have become unfamiliar. This study is based on the observation of patients while they were undergoing treatment for carcinoma of the right segment of colon.

The anemia produced by carcinoma of the proximal portion of the colon may be due to any one or a combination of the following: the carcinoma, the secondary infection, a toxin, metastasis, changes in the intestine secondary to obstruction, hemorrhage, or an iron deficiency.

Investigation of the concentration of iron in the serum of patients with carcinoma of the right half of the colon appeared to offer a different method of studying the anemia. Study of serum iron is necessary in view of the work of Moore, Doan and Arrowsmith,¹³ which seemingly assigned the role of transporting iron to the serum. If the values for the serum iron are found to be abnormal, the concentration of the serum iron with other clinical, laboratory, and pathologic findings in a series of cases of carcinoma of the proximal portion of the colon might be of value in evaluation of the mechanism of production of the concurrent anemia.

METHODS

The methods employed, both in collecting the samples of blood and in the laboratory procedures dealing with determination of the concentration of iron in the serum, were utilized essentially as described by Moore, Arrowsmith, Quilligan and Read.¹⁴ Each estimate for the serum iron value was obtained by averaging the concentration in two samples of blood which were collected separately. Such a precaution afforded a check on the accuracy of the method used and reduced to a minimum the chances of error from contamination. In none of the cases was the variation greater than 10 micrograms per 100 c c, a variant within the limits of error for the technic utilized.

In addition to determinations of the concentration of serum iron,

* An abridgment of a thesis submitted by Dr. Clark to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Surgery.

† Since this paper was written Dr. Clark has joined the armed forces and is now Major, Medical Corps, Army of the United States.

this study included estimation of erythrocyte count, examination of blood smears and evaluation of the color index, volume index, saturation index and hematocrit readings. Additional laboratory investigations in certain instances included analysis of gastric contents, the determination of the sedimentation rate, reticulocyte count and concentration of bilirubin, and the van den Bergh reaction.

The concentration of hemoglobin was determined by the method of Sanford and Sheard,¹⁸ using their photo electrometer. This instrument was standardized at frequent intervals by comparing results with those obtained by gasometric determinations for oxygen capacity of the blood as devised by Van Slyke and Neill.¹ The percentage of error was maintained below ± 2.0 per cent. The remaining procedures were in routine use in the laboratory and have been described in a recent standard treatise on laboratory technique.²⁰

Clinical features bearing on the investigations have been considerations of age, sex, type and duration of symptoms and previous therapy. The pathologic data pertained to the size, grade, type and situation of the carcinoma and the frequency of its association with ulceration, metastasis, perforation, obstruction or other structural changes in the involved segment of colon.

RESULTS

The studies herein reported were made on twenty-three patients with a carcinoma in some portion of the colon. Twenty-one of the twenty-three patients had a lesion involving the proximal portion of the colon. One of the remaining two patients had carcinoma of the splenic flexure and one had carcinoma of the rectosigmoid. Both patients had anemia and were included for purposes of comparison. An evaluation of the clinical features in each case was made in attempting to determine what factors could exert an influence on blood formation. No correlation between any particular symptom and the anemia could be made. However, it was observed that diarrhea, indigestion, anorexia, nausea or excessive pain was present, separately or combined, in practically all instances and that the nutritional status of the patient (average loss of weight 16.3 pounds) was greatly altered. It is readily conceivable that such disturbances could result in a decrease in the amounts of substances which are ordinarily eaten and absorbed and are available for combating anemia.^{11, 12}

The age variant of the twenty-one patients who had carcinoma of the proximal portion of the colon (thirty-eight to seventy-two years) and the sex (ten women and eleven men) appeared to have no bearing on the degree or frequency of anemia. It was surprising how long symptoms had been present before the patients came for consultation. Fifteen of the twenty-one patients had had symptoms for one to two years or more. The frequency of occurrence of low concentration of hemoglobin increased with the duration of symptoms.

The occurrence of anemia in a case in which carcinoma is situated in the right half of the colon is not coincidental. Repeated reports^{1, 5, 15, 16} of studies conducted on large series of patients attest to the occurrence of anemia in about 50 per cent of cases while only about 5 per cent of patients with a carcinoma in the left half of the colon have abnormal blood findings.

It has been demonstrated¹ that ulcerating carcinomas of the proximal portion of the colon are larger than those in the distal portion of the colon or in other hollow viscera.

The specific distribution of the cancerous process in the twenty-one consecutive cases of malignant lesions of the proximal portion of the colon studied was thirteen in the cecum, five in the ascending colon and three in the hepatic flexure.

It is of interest that the grade of activity³ of the carcinoma cells was inversely proportional to the degree of anemia. That is, the most profound anemia was associated with a low grade of malignancy. The carcinomas of a low grade of activity had been present a longer time than those of a high grade of malignancy and prolonged surface hemorrhage could have brought about depletion of the iron reserves. Ulceration was present in nineteen of the cases and surface hemorrhages, usually of a degree which was not macroscopic in the feces, had undoubtedly occurred for a considerable time before resection. Obstruction is not a characteristic feature of malignant lesions of the proximal part of the colon and complete obstruction is very rarely encountered unless the growth has become so extensive that it involves the ileocecal valve. Complete blockage of fecal current had not occurred in any case in this series although in four instances the tumor had entirely encircled the lumen of the bowel and in a total of eight cases an obstructing tendency was manifest. The anemic trend in these cases was present before and not after symptoms of obstruction occurred. Likewise, studies by Welch, Mayo and Wakefield²² have demonstrated that in cases in which malignant lesions were situated in the colon (involved the ileocecal valve) there were no histologic changes in the proximal and distal segments of the colon. Perforation should also be of interest in considering the various features capable of producing anemia as it adds the element of infection. A tendency to perforation was evident in seventeen of the cases as the carcinoma had penetrated the layers of the wall of the colon. However, infection arising from the perforation was of consequence in only one instance. In this case (case 16) a huge abscess developed in the right lower quadrant of the abdomen following ileocolostomy. Anemia had been present for some months previously and remained unchanged following the perforation.

Metastasis had occurred to the regional lymph nodes in nine of the cases, and liver in one case, and in another generalized dissemination of the cancerous process was demonstrated. The highest value for

hemoglobin (case 1) was found in conjunction with the most extensive local growth, regional metastasis and involvement of the liver. Metastatic carcinoma did not appear to affect any concurrent anemia.

Fig. 149—Values for erythrocytes and hemoglobin in association with carcinoma of the right half of the colon

Fig. 150—Values for hemoglobin and hematocrits in association with carcinoma of the right half of the colon

Characteristically then, a low-grade, large, ulcerating penetrating nonobstructing carcinoma was found in association with metastasis in approximately 50 per cent of the cases. It appears significant that the

largest carcinomas of the colon and those that exist for the longest period before producing symptoms are situated in that part of the colon in which cancer is most frequently associated with anemia

Fig 151—Values for mean corpuscular volumes and hemoglobin in association with carcinoma of the right half of the colon

Fig 152—Values for hemoglobin and color index in association with carcinoma of the right half of the colon

Characteristics of the Blood.—In this series of cases (fig 149) the erythrocyte count was found to be high when the determinations were reviewed, being below four million in only three cases and in

each of these severe anemia was present. Hemoglobin deficiency was the outstanding feature of the blood picture (in thirteen cases the value for hemoglobin was less than 10 gm per 100 c.c. of blood) As would be expected from the comparative values for the erythrocytes and hemoglobin (fig 149) the morphologic features of the blood were characterized principally by a decrease in the hemoglobin of the erythrocytes. This hypochromasia varied from essentially normal cells to a marked decoloration as the values for the hemoglobin decreased. Of the twenty-one patients with lesions of the right colon, only two presented approximately normal blood pictures, nineteen exhibited slight to marked hypochromasia and nine showed varying degrees of microcytosis (figs 149 and 150) The microcytic character of the erythrocytes occurred in those instances in which the concentration

Fig 153—Values for hemoglobin and serum iron in association with carcinoma of the right half of the colon.

of hemoglobin was very much below normal. A typical severe anemia that accompanies carcinoma of the right segment of the colon may be classified as a hypochromic microcytic anemia (fig 150)

Other related blood findings were reticulocyte counts ranging from 0.5 to 1.5 per cent before treatment, hematocrit variations from low normal of 42 per cent to 27 per cent (fig 150), the decrease corresponding well to the decrease in hemoglobin. The volume index and mean corpuscular volume were below unity (fig 151) the disparity increasing as the degree of anemia became more profound and true microcytosis developed. A low color index was a characteristic feature (fig 152) and in five cases a slight to moderate 'left shift' of the polymorphonuclear leukocytes was the only other alteration of importance. There was no evidence in the circulating blood of hemolysis

and even in the presence of severe anemia the concentration of serum bilirubin and the van den Bergh reaction were normal. Essentially the same type of blood picture was present in the two cases in which the lesion occurred in the left half of the colon.

In attempting to correlate the association of a hypochromic microcytic anemia and carcinoma of the right half of the colon, the various causative factors of a hemoglobin deficiency anemia are to be considered. One of the most obvious essentials for elaboration of hemoglobin is iron. An iron deficiency results in a lowered concentration of hemoglobin and a decrease in the size of the erythrocytes.⁸ Therefore, since the type of anemia encountered in these cases was one that is associated with a lack of iron, studies of complete iron metabolism suggest a mode for estimating the relationship of iron and anemia. However, even if complete studies of such a nature could be conducted on very ill patients, the data thus obtained would be circumstantial since the actual quantity of iron absorbed and excreted could

TABLE 1—AVERAGE BLOOD FINDINGS IN TWENTY-ONE CASES OF CARCINOMA OF THE COLON AND IN FIVE NORMAL PERSONS

Status	Hemoglobin, gm. per 100 c.c	Erythrocytes, millions per cu mm	Hematocrit Reading, per cent	Color Index	Serum Iron, micrograms per 100 c.c
Normal	15.2 to 17.2	5.00+	46.5 to 51.1	1.0	99 to 158
Cancer of colon	4.4 to 13.6	2.40 to 5.89	27.5 to 42.1	1.0 to 0.5	22 to 76

not be determined. The transport fraction of blood iron should afford a much better estimate of the iron available for combating anemia.¹³ Such determination made on the blood serum of patients with lesions of the proximal part of the colon proved most illuminating (fig. 153).

The values for iron in the serum of patients with right colonic lesions are shown in figure 153 and these values vary markedly from those of normal individuals. A summation of the blood findings in five normal individuals and in the twenty-one cases is given in table 1.

In cases in which the concentration of hemoglobin was high the concentration of serum iron frequently was low (fig. 153). The patient with low normal concentration of hemoglobin and slightly anemic blood findings had a maximal concentration of from 60 to 76 micrograms of iron per 100 c.c. and a minimal concentration of 30+ micrograms per 100 c.c. Even these maximal values were considered in the lower range of normal by Moore and his coworkers,¹⁴ but are decidedly under the minimal values demonstrated in the five normal persons used for controls in this study.

The concentration of serum iron was definitely lower for the patients who had a moderate to severe anemia than it was in those with a low normal or slightly decreased concentration of hemoglobin. The concentration of iron varied from a minimum of 21.9 micrograms to a maximum of 48.3 micrograms per 100 c.c. of serum. These values for serum iron are as low as any noted in the literature on deficient iron metabolism and demonstrate a persistent decrease in this fraction so marked as not to be ignored.

The effects of iron therapy upon the concentration of serum iron and the blood as a whole furnish the final evidence that must be obtained to incriminate the iron metabolism as the element at fault in the production of the anemia under consideration. Such effects were observed (1) before operation, (2) after an exclusion procedure (ileocolostomy), and (3) following resection of the involved segment.

In only one case was the patient observed long enough before operation to permit the employment of adequate iron therapy. The concentration of serum iron could not be obtained in this case, therefore, it is not included in any subsequent part of this paper. When the patient presented himself for examination he was found to have a marked hypochromic, microcytic anemia accompanying a carcinoma of the ascending colon which had metastasized to the liver. The concentration of hemoglobin was 6.6 gm. per 100 c.c. of blood. The erythrocyte count was 3,450,000 and 1.5 per cent of the erythrocytes were reticulated. With no other therapy but 12 grains (0.73 gm.) of ferrous sulfate daily for seven weeks, the concentration of hemoglobin rose to a maximum of 11.4 gm. per 100 c.c. and the erythrocyte count increased to 4,650,000. The reticulocytes at the same time constituted 3.5 per cent of the erythrocytes.

Seven patients were observed following simple ileocolostomy. It was desirable to see just what effect exclusion of the lesion from the fecal current and relief of any incomplete obstruction that might be present would have upon the blood findings without iron therapy. Five patients therefore received no iron therapy and maintained approximately their status quo in the short interval of about three weeks before resection. One patient (case 5) was given iron orally and one patient (case 8) received liver and stomach concentrates. A comparison of these two patients receiving contrasting therapies affords an excellent insight into the problem. The patient who received iron therapy was able to maintain his concentration of hemoglobin and serum iron. The patient to whom the antianemic factor was administered became more anemic in a corresponding interval of two months. In both instances the cancer remained in situ and continued to bleed as demonstrated by repeatedly positive tests for occult blood in the stools.

Following resection of the involved segment of intestine, the rate of blood restitution with and without therapy was noted. The variation

TABLE 2—HEMATOLOGIC FINDINGS BEFORE AND AFTER RESECTION OF INTESTINE FOR CARCINOMA

Case	Specimen of Blood Obtained	Days	Hemoglobin gm per 100 c.c.	Erythrocytes millions per c.c.	Hematocrit Reading, per cent	Serum Iron, micrograms per 100 c.c.	Therapy
Two*	Before resection		12.6	4.76	41.7	39	12 grams of ferrous sulfate, daily for 20 days
	After resection	18	12.5	4.53	39.8	44

in the blood findings is recorded in table 2. The first seven patients received iron therapy, iron was withheld from the remaining five. Of the seven patients given medicinal iron the first three (table 2) exhibited only a moderate decrease in the initial concentration of hemoglobin and showed little change following resection and therapy. The remaining four, who had moderate to severe anemia, showed a decided response to oral administration of iron. Two of the latter patients (cases 11 and 19) are particularly interesting. Both received less than 1 gm of ferrous sulfate daily for eight and seventeen days, respectively, and demonstrated rapid progress toward normal hematologic findings. In the group of five patients who received no medicinal iron, the absorbed dietary iron must have been utilized in any regeneration of hemoglobin that occurred. The percentage of utilization of dietary iron is a factor that is influenced by many different conditions of the gastrointestinal tract.^{6, 8} The variation in absorption and possibly in utilization of food iron is amply evidenced by these patients. The first two patients of this group showed absorption and utilization, as borne out by an improvement in the concentration of hemoglobin and an increase in the serum iron. The remaining three showed no evidence of absorption as the concentration of hemoglobin and serum iron remained unchanged.

In all cases, following resection of the cancerous segment of bowel, elevation of the hemoglobin values were accompanied by a return of the concentration of serum iron to a more nearly normal status regardless of the source, either dietary or medicinal, of the absorbed iron. The definite impression is obtained that iron therapy accelerates the recovery from the anemia, and that the more marked the hypochromic anemia, the greater the need for iron. The variable in this group of cases that continues to be confusing is that related to absorption, and this can possibly be eliminated only when a suitable preparation of iron for parenteral administration is available.

We have observed that patients with carcinoma of the left half of the colon who have an anemia (case 22) likewise demonstrate a lack of recovery from anemia if the concentration of serum iron shows no evidence of iron absorption.

In five cases resection was effected by the process of exteriorization and thus the colon was isolated from regions of absorption during the period of recovery from the anemia. As may be observed (table 2) this did not prevent the absorption of iron needed for elaboration of hemoglobin.

COMMENT

The concentration of hemoglobin was in the low normal range even in cases in which the highest concentration was obtained. Hypochromasia was the outstanding characteristic until the concentration of hemoglobin became very low. When this occurred the prevalence of microcytic erythrocytes in the circulation was increasingly observed. The color

index was below parity in all instances in which actual anemia was encountered, the more severe the anemia the less was the color index. Toxic destruction of the erythrocytes was not in evidence as they were generally not materially decreased in number and excessive regeneration was not present. The hypochromasia also increased and the color index decreased with the severity of the anemia. Such a condition does not obtain in the presence of excessive liberation of hemoglobin owing to abnormal destruction of erythrocytes by a hemolytic toxin. The toxin most likely to result from a lesion of this nature would be one elaborated by the cancer itself or by bacterial invasion of the ulcerated cancerous surface. Toxins from the presence of the cancer cells have not been demonstrated. In cancer, which is not associated with bleeding anemia rarely occurs until metastasis is present. As an example, in cases of nonulcerating cancer of the breast the value for the hemoglobin usually is normal.

It would not be expected that a cell which has reverted to its embryonal form would elaborate a highly specialized substance which would have a specific action in the destruction of blood. Also its function of absorption would be expected to be materially deterred rather than enhanced by the lack of differentiation to adult form, as occurs in cancer cells. The presence of a cancer, if such a toxin were produced, would always result in anemia, which was not the finding in this study. The adjacent mucous membrane is in no wise changed by the presence of a nonobstructing carcinoma, therefore its likelihood of absorption of toxins can be assumed to be the same as that of a normal person. This leaves bacterial invasion of the cancerous growth and its effect upon the blood picture by its concomitant infection to be considered. Actually, in five of the twenty-one cases there was evidence of infection, as demonstrated by the polymorphonuclear leukocytes. The effect of infection upon the erythrocytes is spoken of as toxic suppression of the bone marrow function as related to hemapoiesis.¹⁷ In such a condition not only the elaboration of hemoglobin is at fault but the maturation of the erythrocytes also is apparently delayed. This results in a decrease in both elements in the circulating blood. A normocytic anemia would be expected with anisocytosis, poikilocytosis and decided changes in the polymorphonuclear elements. Such is not the case in anemia associated with cancer of the right half of the colon as many of the patients who had severe anemia were entirely devoid of toxic manifestations. Even in two instances in which severe infection developed following operation there was no particular change in the degree or type of anemia. It is conceivable that a severe infection in a case of hypochromic anemia could increase the anemia by increasing the demands already being exerted on the hemapoietic system, by rendering the patient so ill as to prevent proper ingestion of food or medicinal iron and by retarding the formation of hemoglobin along with a general depression of metabolic activities.

If the anemia that occurs with a cancer situated in the right colon is not due to absorption of toxin, could it conversely be the result of a decreased absorption of an antianemic element from the diseased segment of bowel? It has been demonstrated that the right half of the colon or even the whole colon can be excluded from absorption and the individual recover from the anemia. Therefore, malabsorption from this portion of the bowel would not be evinced by the production of an anemia.

What effect could cancer of the right half of the colon exert on the formation of hemoglobin to render it deficient when cancer in the distal segment of colon rarely exerts a similar influence? It could cause an excess demand for hemoglobin by long continued chronic hemorrhage. It has been demonstrated that the largest and most friable malignancy of the entire gastro-intestinal tract can and does exist in the proximal part of the colon for a long time without producing obstruction or other severe symptoms.¹ To lose blood means the loss of iron, and since the dietary iron absorbed at one time is very small,^{8, 10} the iron lost by hemorrhage from such a growth could readily exceed the daily intake of iron in the food. If such should continue for many months it may readily be seen that the iron reserves available for the formation of hemoglobin would be depleted and a subnormal condition of the blood supervene. Although the lesions in the left half of the colon bleed frequently, the bleeding is from a small tumor and is readily discovered, as the red blood may be expelled unmixed with feces. Lesions of the left half of the colon rarely had existed for anything like the duration of the lesions of the right half of the colon without producing an obstruction. When an anemia does occur in association with carcinoma of the distal portion of the colon it is a hemoglobin deficiency anemia and is in no wise different from the anemia observed in cases of carcinoma of the right half of the colon.

With abnormal loss of iron through chronic hemorrhage there is an increased demand for it, of course.²³ This demand can be met by the stored iron only so long as it is not depleted. If hemorrhage continues the absorbed, ingested iron must be adequate or hypochromic anemia will occur.^{7, 10} Is it possible for a carcinoma situated in the proximal part of the colon to exert an effect upon the absorption of iron from the intestinal tract, and if so, is this effect more pronounced than that exerted by lesions in the distal portions of the colon? It appears from the comparative study of the symptoms produced by cancer in the proximal and in the distal portions of the colon that just such a situation occurs. The principal symptoms of cancer of the right half of the colon, other than anemia, are indigestion and diarrhea. The indigestion is apparently reflex as the association of disturbances in the cecum and ascending colon and referred epigastric pain and discomfort is notorious. Nausea and vomiting, gaseous distention, epigastric pain, anorexia,

and preprandial and postprandial discomfort are all encountered characteristically in cases of carcinoma of the right half of the colon. Such symptoms greatly limit the intake of food and the tendency is to eat light foods which have little value as a provider of dietary iron. In cases of cancer of the distal portion of the colon the symptoms are usually local, and until obstruction has occurred deficient intake of food is not likely to be a factor.

Other factors influencing the absorption of iron from the gastrointestinal tract are more in evidence in cases of carcinoma of the right half of the colon than in cases of carcinoma of the left half of the colon. In eighteen of the twenty-one cases of cancer of the right half of the colon analysis of the gastric contents was made, no free hydrochloric acid was present in eight of these cases and in several of the cases an excess of mucus was present in the gastric contents. It has been demonstrated^{2, 4, 9} that both of these factors can cause a deficient absorption of dietary iron.

SUMMARY

The type of anemia that occurs with cancer of the proximal portion of the colon has been observed to be the same as that produced by a deficient supply of iron for elaboration of hemoglobin. The abnormal demands made upon the iron supply of the body have been noted to be increased in instances in which the growth is situated in the proximal segment, while the ingestion and absorption of dietary iron appeared to be more retarded than they were when the growth was situated in the distal portion of the colon. The presence of other associated deleterious factors influencing absorption has been surmised. Study of the concentration of serum iron has furnished additional confirmation that a deficiency of iron is present. In all cases of cancer of the right half of the colon the concentration of serum iron was low. If severe anemia was present, a very marked decrease in the concentration of serum iron was observed. The anemia could apparently be arrested, with the cancer in situ, following iron therapy if the iron was of sufficient amount and was absorbed. Recovery from the anemia following removal of the cancer was demonstrated to be dependent upon adequate absorption of iron. Administration and absorption of iron following resection of the involved segment of colon resulted in a return of a normal concentration of serum iron and hemoglobin. Anemia accompanying carcinoma of the distal portion of the colon has been observed in two instances to be similar to that observed in conjunction with carcinoma of the proximal portion of the colon.

TESTS OF LIVER FUNCTION

JAMES F WEIR

THE diagnosis and management of diseases of the liver and biliary tract fundamentally rest on the evaluation of clinical data. The procedures have been established through long periods of clinical practice and have been reasonably satisfactory. There are certain instances in which a clinical diagnosis cannot be made with certainty. In some such cases, the patients have been denied the possible benefits of surgical exploration, in other cases surgical procedures have been employed to the detriment of the patient, particularly if parenchymatous disease of the liver has been present. During the past two or three decades, much new knowledge concerning the physiology of the liver has been developed and, as a corollary of this attempts have been made to determine the nature, extent and significance of functional abnormalities in various types of disease of the liver or biliary tract. This has led to the development and use of many tests of liver function. In the use of such tests, attempts have been made to apply them to the differential diagnosis and management of such diseases with, unfortunately, an unwarranted halo of importance and significance. Actually these tests are somewhat limited in value yet no apologies are needed for their judicious employment.

Such tests presuppose a knowledge of the functions of the liver and there are many of these. Approximately thirty-three different, though related, functions of the liver cells have been listed and it is estimated that at least 100 chemical activities are known to occur in the liver. In view of this, the following question may be asked, "What is a liver function test?" One answer, elementary and facetious, might be, "Some laboratory procedure that reveals something wrong with the liver." That something is wrong is usually known before employment of the procedure, from clinical observation, such as enlargement of the liver, jaundice or ascites. This answer may be satisfactory in cases in which clinical evidence of disease is absent. Perhaps a better answer would be, "A procedure that shows a disturbance, and perhaps the degree of such disturbance, in some particular function of the liver." Obviously in view of the many functions of the liver, its known large reserve and great regenerative capacity, no "miracle" test can be expected, that is, no single test can be anticipated that will determine deviations from normal of even a few major functions of the organ, let alone all of them.

Some authors claim that the chief value of these tests is the detection of early functional disturbance or focal disease such as carcinoma or abscess. Because of the known large reserve capacity, severe and ex-

tensive damage is necessary before positive tests may be obtained in such conditions. Consequently, some physicians would say that the tests lack sensitivity. Others claim that the tests are too sensitive. Positive results may be obtained but no clinical signs of disease of the liver may be apparent or develop. Rafsky, and Newman, for example, have reported a considerable group of aged persons on whom positive tests were obtained in the absence of clinical evidence of disease of the liver. The question may then be asked, "Is a positive test an indication of disease of the liver or only of a dysfunction (as diarrhea in a case of irritable colon), and if it is an indication of dysfunction what is its significance?" Answer to this question is difficult to give. The significance of minor deviations from normal are particularly difficult to evaluate. The results must always be interpreted in association with other available data. In some instances, the findings are significant, in others, correlation of the findings is impossible.

If tests are to be used clinically, they must be readily performed, reliable, and give some worth-while information from a diagnostic, therapeutic or prognostic standpoint. In addition, the results must be capable of being interpreted easily. Probably about seventy-five to 100 tests for liver function have been devised. The large number of these that have been used and discarded is evidence of their failure to meet the criteria which I have mentioned. The multitude of tests and the claims and counterclaims made in regard to them have created a very confusing situation, particularly for the general practitioner. It would seem well, therefore, to consider a few of the more simple procedures and their practical application.

In such a consideration, certain facts should be pointed out. First, diagnostic procedures should be distinguished from tests for liver function, thus, duodenal drainage and examination of the stools for bile are best classified as diagnostic procedures because they are primarily used to determine the patency of the bile ducts. Such procedures leave much to be desired.

Second, there are two groups of cases in which tests of liver function are commonly used (1) cases of suspected liver disease in which jaundice is absent, and (2) cases of jaundice. In the first group, the dye excretion tests and van den Bergh test are particularly valuable. In the second group, it is necessary to determine whether the jaundice is hemolytic, obstructive or hepatogenous. Hemolytic jaundice is usually readily distinguished by clinical and hematologic studies, and the van den Bergh test is also helpful. The last two types of jaundice usually are distinguished by clinical study, chiefly by the history in regard to pain or exposure to infection and hepatotoxins, by physical evidence of abdominal tumors, and by employment of diagnostic procedures to determine the patency of bile ducts. Some aid in this distinction may be obtained from the use of some of the tests of liver function, such as the distribution of urobilinogen in the urine and feces, the van den

Bergh test, the galactose tolerance test and the partition of cholesterol in the plasma

Thus, then, is the first practical use of tests of liver function, that is, assistance in the differential diagnosis of various types of jaundice. Their second use is for the confirmation of the presence of liver damage in cases in which it is suspected and the evaluation of the extent of liver damage in cases in which the presence of disease of the liver or biliary tract is known. The qualitative and quantitative determination of serum bilirubin by the van den Bergh test, dye excretion tests, hippuric acid synthesis, galactose tolerance test, blood prothrombin time, partition of cholesterol in the blood and the value for the protein in the blood are procedures most commonly used in the study of such conditions but they give information of variable value. Many of these are not truly functional tests but laboratory procedures which throw some light on one or another aspect of disease of the liver. In the interpretation of the results of such tests in the presence of jaundice, it should be remembered that there is seldom any case of jaundice pure in type. For example, severe hepatic damage may occur in cases of obstruction of the biliary tract or in hemolytic processes, and the tests may be valuable in these types of disease as well as in primary parenchymatous disease of the liver.

Third, and finally, there is the question of progression of activity of disease of the liver or recovery. Repetition of some of these tests aids in the determination of this point. Some physicians claim that the cephalin-cholesterol flocculation test is of particular value as such an indicator.

Some of these tests will now be considered individually and in more detail. The first of these is the *van den Bergh test*, which is used to determine the type and quantity of bilirubin in the serum. It also can be applied to the duodenal contents and urine. Various modifications of the original test have been developed.¹ Prior to two years ago, we employed the technic of Thannhauser and Andersen but since then the technic of Sepulveda and Osterberg has been used. This permits the quantitative determination separately of the indirect and direct reacting bilirubin in the serum in any given case. In health, the value for the bilirubin is less than 0.6 mg. per 100 c.c. of serum and it reacts indirectly with Ehrlich's diazo reagent. In pathologic states such as pernicious anemia, congenital hemolytic icterus, other hemolytic conditions and familial hyperbilirubinemia, the reaction is characteristically indirect. In these conditions the concentration of the bilirubin in the serum usually is variably increased. In many cases of cirrhosis, metastatic tumors of the liver and other pathologic conditions of the liver without evident jaundice, the reaction to the van den Bergh test may be indirect. This type of reaction does not exclude any of these pathologic processes. Pigmentation, such as that due to carotene and atabrine, must be distinguished from icterus. In cases in which pig-

mentation is due to carotene or atabrine, the concentration of serum bilirubin is normal and the reaction is indirect. A direct reaction always is a pathologic finding and is commonly encountered in the various forms of obstructive and hepatogenous jaundice. Such a reaction also is present in the latent jaundice at times seen after biliary colic, in acute cholecystitis, in metastatic tumors of the liver and in many cases of chronic and even acute hepatitis. In the presence of a hemolytic process, a direct reaction indicates an associated hepatic or biliary disorder. Little attention from a clinical standpoint need be given to biphasic or delayed direct reactions.

The quantitative determination shows the degree of retention of bilirubin and its fluctuations from time to time. In many instances estimations every few days are necessary to determine whether the jaundice is stationary, increasing or decreasing in severity. In obstructive jaundice due to stone in the common bile duct, the average value for the serum bilirubin is 10 to 15 mg per 100 c c. Fluctuations frequently occur and there is a general tendency for the bilirubinemia to decrease. In neoplastic obstruction of the common bile duct, average values are higher, that is 20 to 30 mg per 100 c c. Fluctuations seldom occur and the jaundice is persistent. In parenchymatous disease of the liver, the degree of icterus is variable. In some cases, very mild degrees of bilirubinemia are encountered. On the other hand, some of the highest concentrations (70 to 100 mg per 100 c c) encountered are due to this type of disease of the liver. The higher concentrations are indicative of more serious disorganization of the liver. In obstructive jaundice, similarly high concentrations (that is, much above the average concentration) are indicative of an associated hepatic degeneration.

The *icterus index* is a simple and approximate method of following the degree and variations of bilirubinemia in any case of icterus and is used in many laboratories.

Dye excretion tests are frequently used in the determination of liver function. Various dyes may be used, such as phenoltetrachlorophthalein, tetraiodophenolphthalein, Bengal red and bromsulfalein. These tests depend on the rate of disappearance of the dye from the blood stream. It has been our custom at the Clinic to use bromsulfalein. We inject 5 mg of the dye per kilogram of body weight of the patient, remove a specimen of blood in one hour and determine the amount of dye remaining in the blood with a block colorimeter. Normally, little remains in the blood at the end of one hour. The presence of 40 per cent or more indicates a high degree of retention. Various modifications of this technic have been made but I doubt their practical importance. This is one of the best tests of liver function in cases in which jaundice is not present. The presence of jaundice is a contraindication to the use of this test. When jaundice is present, the test merely shows the impairment to be expected, as indicated by retention of bilirubin and furnishes no additional information. The test is to be used in cases

in which disease of the liver is suspected when jaundice is absent. These diseases include enlargement of the liver and spleen, suspected metastatic tumor or abscess, ascites and toxic hepatitis such as may occur in cases of exophthalmic goiter, toxemias of pregnancy, many infections, poisoning with various therapeutic and industrial chemicals and many other conditions. Normal values usually are obtained in abdominal enlargement due to ovarian cysts, peritoneal carcinomatosis and tuberculous peritonitis. In cardiac disease with decompensation and chronic passive congestion, a moderate to high degree of retention of the dye usually is encountered. Ascites due to portal obstruction from canalized portal thrombosis usually gives normal values but some disturbance of excretion of the dye occasionally is found. In cases of suspected metastatic tumors or abscess of the liver, and occasionally in cirrhosis the values may be normal. In cases of splenomegaly in which splenectomy is being considered, high degrees of retention may be encountered, indicating a high surgical risk and a poor prognosis. In some cases in which the patients are in reasonably good health mild degrees of retention of the dye occasionally are encountered but no definite disease of the liver can be demonstrated and no satisfactory cause for the retention can be found. In some instances, dehydration and starvation may be etiologic factors. In other instances, these are absent but in spite of lack of any explanation, the findings are probably of some significance.

The *hippuric acid test* depends on the ability of the liver to furnish glycine to permit the synthesis of hippuric acid from benzoic acid (administered as sodium benzoate). It is claimed to be a test of the detoxicating function of the liver. The presence of disease of the kidney should be excluded before this test is employed. The amount of hippuric acid excreted in the urine is determined gravimetrically. After administration of 6 gm of sodium benzoate, at least 2.5 to 3 gm as hippuric acid should appear in the urine in four hours. Less than 1.5 gm. is indicative of impairment of liver function. The test does not aid in distinguishing obstructive jaundice from hepatogenous jaundice. In cases in which jaundice is absent, the results parallel those obtained with the bromsulfalein test. An intravenous method of performing the test has been devised and is employed by many physicians.

The *galactose tolerance test* is one of the sugar tolerance tests used to determine deviations of the normal function of the liver to metabolize carbohydrates. Galactose is chiefly utilized by the liver, and in the performance of the test it may be administered orally or intravenously. When the galactose is administered intravenously, the test is spoken of as the "galactose clearance test." In using the test it is necessary that the presence of diabetes mellitus be excluded. If oral administration is employed, 40 gm of galactose in 500 c c of water is given and the urine is collected over a five hour period and examined for sugar. Normally, less than 3 gm of sugar should be excreted. Excretion of more than 5 gm

is indicative of severe hepatic damage. In acute hepatitis, positive tests may be obtained early (less than two weeks). In obstructive jaundice, the test may become positive at the end of two weeks. In our experience at the Clinic, the test has been found mildly positive in 50 per cent of cases of malignant obstruction and in 25 per cent of cases of obstruction due to stone or cicatricial stricture. Normal results do not exclude the possibility of parenchymatous origin of jaundice.

The *prothrombin time* should be determined in all cases of jaundice, particularly if the disease is surgical, in which case it should be determined during the preoperative and postoperative periods. In the laboratories of the Clinic, the method of Quick, as modified by Magath,² is used. With this method, the normal values are eighteen to twenty seconds. Elevation of the prothrombin time may be due to deficient intake, deficient absorption or deficient utilization of vitamin K. Deficiency of intake is seldom a factor in jaundiced conditions. A deficiency of absorption is common in the acholia of jaundice. It also occurs in intestinal disorders such as those associated with sprue. Deficiency of utilization of vitamin K is encountered chiefly in parenchymatous disease of the liver. In this disease, the vitamin K is not converted into prothrombin, and if the damage to the liver is severe, administration of vitamin K will not control the hypoprothrombinemia and its associated hemorrhagic manifestations. The degree of this failure is an indication of hepatic insufficiency. Data accumulated in the past two years indicate that larger doses than formerly employed may be advisable when small doses are ineffective. Vitamin K should be administered in all cases of jaundice, whether or not the prothrombin time is prolonged. This is particularly true in cases in which operation is to be performed and the administration should be continued during the postoperative period.

Another test is the determination of the distribution of *urobilinogen* in the feces and urine. Much of the recent work in this field has been done by Watson and by Steigmann and Dyniewicz.^{5, 6} The methods are tedious and complicated but Watson has simplified the procedure to a great extent. Normally, much of the bilirubin of bile entering the intestine is changed to urobilinogen. Much of this is absorbed into the blood stream, passes to the liver and is reconverted to bilirubin. Under normal conditions, 30 to 200 mg of urobilinogen is excreted in the feces during twenty-four hours. Small amounts appear in the urine (0.2 to 3 mg in twenty-four hours). Persistent absence of urobilinogen from the feces (and urine) indicates that bile is not entering the intestine, and hence complete obstruction of the biliary passages. This is most frequently seen in cases of malignant tumors but occasionally occurs from a stone impacted in the common bile duct and from complete cicatricial stricture of the bile ducts. A marked increase in urobilinogen in the feces (up to 3,600 mg in twenty-four hours) is

encountered in the various hemolytic processes such as congenital hemolytic icterus and pernicious anemia. In diseases of the liver, such as acute hepatitis and active cirrhotic processes, the normal conversion of absorbed urobilinogen to bilirubin is interfered with and excessive amounts of urobilinogen appear in the urine. In such diseases, there is frequently a decreased amount of bilirubin entering the intestine and, consequently, less urobilinogen can be formed. Nevertheless, increased urinary urobilinogen is the usual finding. In inactive cirrhosis without jaundice, variable amounts of urobilinogen are found in the feces and urine. In these circumstances, interpretation of the results should be made with caution. Summarizing, one may say that the presence of the substance in the feces indicates that the bile passages are not occluded and that excessive amounts in the urine indicate some impairment of liver function or the presence of an associated hemolytic process.

Determination of the concentration of several of the constituents of the blood often gives valuable information on sufficiency or insufficiency of some of the functions of the liver. The *protein content of the serum* normally is from 6 to 8 gm per 100 c.c. In chronic parenchymatous disease of the liver and at times in the latter stages of acute parenchymatous disease, the concentration of the proteins of the blood is reduced. This is particularly true of the albumin fraction, thus reversing the albumin-globulin ratio. The value for the globulin may be increased. The decrease in concentration of the albumin apparently is due to failure of its fabrication by the liver rather than to deficiency of intake or absorption or an abnormal loss. The hypo-albuminemia produces a lowered colloid osmotic pressure of the blood and is a factor in the formation of edema and ascites, which frequently are encountered in chronic disease of the liver. Although hypo-albuminemia is frequently encountered in disease of the liver, there are many instances, particularly those in which the condition is of short or moderate duration, in which normal values for protein do exist and, in rare instances, an increased concentration of protein may be noted.

Abnormalities of the partition of *fats in the plasma* are at times encountered in various types of jaundice. However, little is known of the significance of many of these changes. In general, there is a mild to moderate increase in all the fats of the plasma in obstructive jaundice. This is particularly true of cholesterol and cholesterol esters. The concentration of these two components may be decreased in acute parenchymatous disease of the liver and the ester fraction may be entirely absent. Such absence or a marked decrease of this fraction has been used as a prognostic sign, and often indicates a fatal outcome. Marked increase in the concentration of all of the plasma lipids occurs in certain rare chronic diseases of the liver, such as xanthomatous biliary cirrhosis as well as in other chronic metabolic disorders, such as xanthoma tuberosum. In considering these changes in plasma lipids,

is necessary that the presence of these metabolic diseases, as well as that of diabetes mellitus and nephrosis be excluded Hypolipemia is also encountered in sprue and certain rare diseases of the pancreas

Elevation of the concentration of *blood urea* may occur if involvement of the kidneys develops in the course of disease of the biliary tract or liver Occasionally, a lowering of the concentration of blood urea occurs in cases in which long-standing and chronic disease of the liver is approaching its terminal stage Lowering of the concentration of *blood sugar* and associated hypoglycemic symptoms occasionally may be found in cases of chronic disease of the liver in the absence of any demonstrable pancreatic disorder The concentration of *serum calcium* may be lowered in chronic obstructive jaundice, such as that due to cicatricial stenosis of the common bile duct This apparently is due to deficiency of absorption of calcium caused by the acholia Osteoporosis and spontaneous fractures (particularly of the vertebrae) are usually accompaniments The concentration of *plasma chlorides* and the *carbon dioxide combining power of the plasma* are altered in cases of external biliary fistula especially if the fistula is complete or nearly complete, and in cases in which choleresis is present. Dehydration, hypochloremia, acidosis with their accompanying symptoms ensue

Several *serologic tests* based on alterations of the blood proteins, particularly the globulin fraction, have been developed These include the Takata-Ara, the colloidal gold, and Hanger's cephalin-cholesterol flocculation tests Only the last-mentioned test has any support at present It has been advocated as a means of distinguishing obstructive jaundice from parenchymatous jaundice but these claims have not been substantiated There is some evidence that it may be of some value in the estimation of the activity of hepatic disease

The laboratory procedures and tests of liver function that I have mentioned are the ones that we have commonly employed at the Clinic in the past few years It is still our firm conviction that the diagnosis and management of diseases of the biliary tract and liver are largely based on clinical grounds and that the results of the various tests are rather limited in value The tests do not distinguish obstructive jaundice from hepatogenous jaundice although they may furnish some assistance in such distinction. They do not distinguish acute disease of the liver from the chronic type They do not indicate the cause of cellular disintegration However, some estimate of functional capacity of the liver in several respects can be made from data afforded by several of the tests, particularly with their judicious repetition They afford some aid in following the clinical course of disease of the liver, in determining the risk of surgical procedures, in directing preoperative and postoperative treatment and nonsurgical treatment, and in evaluating the prognosis Although these tests have limitations, the data obtained are usually significant. Interpretation of results may be difficult, especially if deviations from normal are slight Positive

tests are much more significant than negative ones. Negative results do not necessarily exclude the existence of disease of the liver or disturbances of hepatic function. Furthermore in some cases, it seems impossible to correlate all the findings adequately. In such cases, particularly, clinical data should be followed and at a later date the tests may be repeated. Finally, the tests do have a value in teaching the physiology of the liver and in research.

CONSTITUTIONAL HEPATIC DYSFUNCTION

MANDRED W COMFORT

FROM time to time, cases of mild acholuric jaundice, in which hemolytic, hepatic or biliary tract disease is suspected as the cause, are encountered. The abdomen occasionally has been opened without finding disease of the biliary tract or of the liver, and splenectomy, cholecystectomy, cholecystostomy or even choledochostomy has been performed without relief of the jaundice. Medical measures that are used in treatment of hepatic disease likewise have not relieved the jaundice. More recently, jaundice of this type has been the cause for contemplated dismissal of men from the armed forces of our country.

Actually the jaundice in these cases is not due to disease of the blood, liver or biliary tract but apparently is due to an abnormally high threshold for excretion of bilirubin formed at the usual rate. The concentration in the serum reaches 10 to 12 mg per 100 c c, and the van den Bergh reaction is indirect. The jaundice is acholuric in type since bilirubin that gives the indirect van den Bergh reaction is not excreted by the kidneys. It is presumably due to an inborn deficiency of the hepatic cells especially with respect to the excretion of bilirubin. The terms "simple familial cholemia," "simple chronic icterus," "familial cholemia" and "familial nonhemolytic jaundice" have been applied to the condition^{7-10, 15} but at the Clinic we prefer to call it "constitutional hepatic dysfunction" because this term indicates the constitutional nature of the condition as well as the organ now believed to be responsible.

The jaundice may not be noted before examination or may have been apparent continuously or intermittently for years. It may begin at any age and often several members of a family are affected similarly. The patient may be extremely healthy and vigorous but he frequently complains of lack of endurance and symptoms of the functional type. He may give a history suggestive of cholecystic disease, with or without stones. Physical examination usually does not disclose abnormalities other than a slight icteric tint to the scleras. The liver and spleen are not enlarged and, as mentioned previously, the urine is free from bile pigment (acholuria). The level of serum bilirubin is increased and the van den Bergh reaction is indirect. The results of morphologic examination of the cellular elements of the blood are normal, as is the fragility of the erythrocytes to hypotonic salt solution. The excretion of urobilinogen in feces for twenty-four hours is said to be normal or slightly decreased.⁵ Other tests of hepatic function have not disclosed dysfunction of the polygonal cells other than that related to excretion of bilirubin. Although roentgenograms of the gallbladder made by the Graham-Cole technic usually disclose normal function, they may dis-

close a poorly functioning or nonfunctioning organ with or without stones. However, this incidental finding cannot be held responsible for the increased level of serum bilirubin giving the indirect van den Bergh reaction.

HISTORICAL MATERIAL

The jaundice of constitutional hepatic dysfunction has been recognized since 1902, when the first of a series of articles by Gilbert and his associates appeared. They called attention to a group of cases in which the bile pigment in the blood was greater than normal. This finding was not associated with enlargement of the liver or spleen. Icterus of the skin and scleras often was apparent. Bile pigments did not appear in the urine. While Gilbert and associates⁷⁻¹⁰ probably included among their cases patients who had hepatic and hemolytic disease, particularly chronic hemolytic icterus and even carotinemia, they deserve credit for recognition of a familial type of acholuric jaundice unassociated with enlargement of the liver and spleen.

Subsequent refinements of diagnosis permitted differentiation of the various disease processes that produce an increased concentration of serum bilirubin giving an indirect van den Bergh reaction but little attention was given to the jaundice of constitutional hepatic dysfunction. In 1935, Rozendaal, Snell and I^{2, 13} reported the first large series of cases of constitutional hepatic dysfunction. This condition was encountered sixty times at the Clinic during a two year period. In 30 per cent of the sixty cases, cholecyctic disease was present. This high percentage suggested that constitutional hepatic dysfunction predisposed to the development of cholecyctic disease but the high incidence may have been the result of the method of selection of cases and the greater frequency with which the concentration of serum bilirubin is determined in cases of cholecyctic disease than in other cases.

Meulengracht in 1939,¹² Dameshek and Singer in 1941⁸ and Curry, Greenwalt and Tat in 1942⁴ discussed the condition and reported cases. Curry and associates described biopsy in the case of a man, fifty years of age, who had constitutional hepatic dysfunction. The hepatic structure and cells were normal. It is interesting that a similar jaundice exists among a certain strain of rats, as reported by Malloy and Lowenstein.¹¹

In 1944, Hoyne and I³ reported a series of thirty-five cases collected from the records of the Clinic over an eight year period since the report in 1935. In case 3 of that report features of chronic hemolytic icterus of the acquired type developed. The spleen became palpable and the erythrocytes became microcytic. The fragility of the erythrocytes increased in the four year interval between the first and second examinations. In other cases of constitutional hepatic dysfunction, microcytosis but not spherical microcytosis has been observed. These findings raise the question of relationship between constitutional hepatic dysfunction and chronic hemolytic icterus, that is whether hepatic

dysfunction of the type seen in constitutional hepatic dysfunction exists in chronic hemolytic icterus

INCIDENCE

The true incidence of the disease among patients who register at the Clinic probably is much nearer the average of thirty per year, as reported in 1935, than the average of four per year, as reported in 1944. The incidence in the latter report would have been greater if the records had been examined of all cases in which the concentration of serum bilirubin with an indirect van den Bergh reaction was greater than 2 mg per 100 c c, this was done in preparing the 1935 report.

DIFFERENTIAL DIAGNOSIS

The recognition of constitutional hepatic dysfunction as a distinct clinical entity is important, not because it affects the health of the individual but because a correct diagnosis avoids the erroneously serious prognosis of true hepatic disease, prolonged medical treatment and unnecessary surgical treatment. The diagnosis would be made more often if all abnormally high elevations of serum bilirubin with an indirect reaction were examined more critically and if the concentration of bilirubin and the indirect or direct nature of the van den Bergh reaction were determined whenever the patient complains of slight jaundice, biliousness, liverishness and sallowness.

The diagnosis of constitutional hepatic dysfunction should be made only after the presence of hemolytic and hepatic disease has been eliminated.

Hemolytic disease is excluded by the absence of history of exposure to toxic, infectious and parasitic agents with hemolytic properties, by the absence of anemia and splenomegaly and by normal morphologic examination of erythrocytes, normal fragility of erythrocytes to hypotonic salt solution and normal excretion of urobilinogen in the urine and feces. Occasionally splenomegaly occurs in a case that otherwise conforms to the definition of constitutional hepatic dysfunction but the latter diagnosis should not be made without further observation and study because of the possibility of atypical hemolytic icterus.

Most types of jaundice due to hepatic disease are excluded at once by the indirect nature of the van den Bergh reaction. The various hepatic functional tests further serve to exclude other dysfunction of the hepatic cells and, inferentially, disease of the hepatic cells. Only when the serum bilirubin responsible for latent jaundice of hepatic disease gives the indirect van den Bergh reaction is a differential diagnosis necessary. Slight latent jaundice due to serum bilirubin giving the indirect van den Bergh reaction often precedes the jaundice of hepatic disease with its more characteristic direct van den Bergh reaction, and may persist for months and even years after recovery from profound damage to the hepatic polygonal cells and after other

hepatic functional tests have become negative. In such cases the history of hepatic damage serves to point to the nature of the disturbance to which the term residual hepatic dysfunction may be applied.

In an occasional case of constitutional hepatic dysfunction the retention of dye in the bromsulfalein test of hepatic function has been increased to 6 or 7 per cent at the end of one hour (normal retention 5 per cent), but in no case has the percentage been increased more than might be accounted for by the human factor. Similarly, the van den Bergh reaction occasionally has been delayed direct instead of indirect, just as it is in the occasional case of true hemolytic icterus but this has occurred only when the concentration of bilirubin was relatively high. When the new technic of Sepulveda and Osterberg¹⁴ has been used in such cases the serum bilirubin has been of the indirect variety. The rate of excretion of bilirubin in congenital hepatic dysfunction is said to be decreased, as is to be expected from the nature of the process.

The jaundice that results from hepatitis associated with cholecystic disease or from obstruction of the duct due to stone is attributable to an increase in the concentration of bilirubin giving a direct van den Bergh reaction. It is accompanied by other characteristic features of disease of the biliary tract, especially colic, and should not be confused with the jaundice of constitutional hepatic dysfunction.

THREE ILLUSTRATIVE CASES

The following abstracts of cases, previously included in the 1944 report by Hoyne and me, illustrate the typical features of constitutional hepatic dysfunction. Jaundice was the sole manifestation of the condition. Disease of the blood, liver, spleen or biliary tract could not be demonstrated.

CASE 1.—A man, aged sixty years, registered at the Clinic in September 1938. He was a highly successful, energetic person who had more than the usual amount of endurance. His sole complaint was recurrent attacks of jaundice associated with fatigue, which he thought were precipitated by worry, nervous stresses, anger and constipation. The jaundice was painless and was not associated with chills, fever, nausea or vomiting. The stools remained normal in color during the attacks. There were no general or abdominal symptoms between attacks. The last two episodes of jaundice had followed renal colic. These attacks had occurred since early life and long had been of concern to both the patient and his physicians. The last attack had occurred several months before registration. His mother, one sister and a niece had experienced similar episodes of jaundice.

The results of general physical examination were negative with the exception of an icteric tinge to the scleras and skin. The liver and spleen were not palpable. Urinalysis and routine serologic test for syphilis gave negative results. The hemoglobin was 14.8 gm per 100 c.c. of blood, erythrocytes numbered 4,790,000 and leukocytes 7,000 per cubic millimeter of blood. Morphologic study of the blood did not disclose abnormality of the cells. Fragility of the erythrocytes to hypotonic salt solution was normal. Roentgenograms of the thorax, gallbladder, esophagus and stomach and bromsulfalein and hippuric acid tests for hepatic function

gave negative results. The concentrations of serum bilirubin were 3.0 and 1.6 mg per 100 c.c. and the van den Bergh reaction was indirect.

The diagnosis was constitutional hepatic dysfunction. The patient recently reported by letter that the episodes of icterus still occurred two or three times a year but that otherwise he had been getting along well.

Comment—The jaundice in case 1 was familial. It was chronic and latent most of the time but overt at intervals when its depth was increased by nervous and emotional factors. Although the attacks had occurred for forty years, they apparently had not affected the patient's health or diminished his endurance, and had not led to the development of disease of the blood, liver, spleen or biliary tract. This case emphasizes the effect of nervous and emotional stress on the depth of the jaundice, an effect that long has been recognized^{1, 5, 6, 12}. The jaundice that occurs after renal colic must be explained on a similar basis.

CASE 2—A man, aged thirty-five years, registered at the Clinic in June, 1938. Except for thyroidectomy in 1930 and appendectomy and tonsillectomy in 1937, his health had been good. His endurance was satisfactory and fatigue occurred only after long periods of intense work. About six months prior to registration the patient had had a short period of malaise with slight jaundice and some loss of weight. The jaundice had persisted after the malaise disappeared and had fluctuated in intensity. Several doctors had diagnosed the condition as acute hepatitis or catarrhal jaundice. A high carbohydrate diet and various medicines including calcium, vitamin B and dilute hydrochloric acid had been prescribed.

The results of general physical examination were essentially negative with the exception of slight scleral icterus. Urinalysis and routine serologic test for syphilis gave negative results. The hemoglobin was 15 gm per 100 c.c., erythrocytes numbered 4,900,000 and leukocytes 8,100 in each cubic millimeter of blood. The erythrocytes were normal in size and shape. Fragility of the erythrocytes to hypotonic salt solution was normal. Gastric analysis after a test meal showed free acidity. Roentgenograms of the thorax, gallbladder and stomach were negative. The basal metabolic rate was -3 per cent. The concentration of serum bilirubin was 2.0 mg per 100 c.c. and the van den Bergh reaction was indirect. Brom-sulfalein test of liver function did not disclose retention of dye.

The diagnosis was constitutional hepatic dysfunction.

The patient was not aware that other members of his family were similarly affected but on inquiry on his return home he found that his brother had a more yellowish tinge to his eyes than the patient. He also learned that his father's family was noted for the yellowish tinge to their complexions, some members of the family having this to a marked degree. His maternal antecedents were fair skinned and there was no history of jaundice among them.

Comment—Case 2 again illustrates that constitutional hepatic dysfunction is compatible with excellent endurance and health. The jaundice was discovered when the patient was thirty-five years of age, and then only because his physician was a careful examiner. Concern about the jaundice was only natural and treatment for hepatitis was without benefit. The patient's anxiety was dispelled when the nature of the condition was explained and only on inquiry was the familial incidence of the condition established.

CASE 3—A woman, aged forty years, registered at the Clinic in December, 1934 Ill health developed in 1919 at the age of twenty five years. There was fatigue, nervousness, insomnia and epigastric distress which appeared soon after, or as long as one hour after, meals and then shifted to the lower portion of the abdomen. The discomfort was accompanied by marked bloating and pressure in the left upper quadrant of the abdomen, palpitation of the heart and dizziness. Vomiting occurred at the time of leaving the table or soon afterward Constipation with the passage of large amounts of mucus was a prominent feature of her problem. The whites of the eyes became yellow with the more severe attacks of nervousness, fatigue and abdominal distress and usually also when she was badly constipated. Other members of the family did not exhibit jaundice.

Vigorous efforts had been made to cure the patient. In addition to various medical measures, appendectomy had been performed in 1919 The jaundice had aroused suspicion of the biliary tract, consequently cholecystectomy had been performed in February, 1933, and exploratory choledochostomy and gastro-enterostomy in October, 1933 Tonsillectomy later was undertaken All surgical procedures, as well as medical measures, had failed to influence the severity of her complaints or the jaundice.

On examination at the Clinic, urinalysis and serologic test for syphilis gave negative results The hemoglobin was 17.4 gm. per 100 c.c., erythrocytes numbered 4,360,000 and leukocytes 8,300 per cubic millimeter of blood. The results of differential count of leukocytes were normal The reticulocytes numbered 0.7 per cent. Morphologic study of the blood did not disclose abnormal cells Fragility of the erythrocytes to hypotonic salt solution was normal Analysis of the gastric contents after a test meal showed small amounts of free acid Roentgenograms of the thorax and colon were normal those of the stomach showed the gastro-enterostomy to be free and the stomach to be normal. The duodenum was not visualized. The concentration of serum bilirubin on two occasions was 2.7 and 3.7 mg per 100 c.c., with an indirect van den Bergh reaction. The bromsulphalein test of hepatic function did not disclose retention of dye

The diagnosis was chronic nervous exhaustion mucous colitis and constitutional hepatic dysfunction.

In a recent letter the patient stated that the scleral icterus still appeared whenever she became markedly fatigued and after spells of severe abdominal distress. A bland anticonstipation diet and an improved program of living had produced improvement.

Comment—The patient in this case complained, as do so many patients who have constitutional hepatic dysfunction, of a multitude of symptoms of the functional type. The jaundice was intensified and became overt under stimulation of increased fatigue and emotional and nervous stress but scarcely could be blamed for the patient's disability. The attacks of jaundice continued in spite of the institution of numerous medical and surgical procedures. The jaundice was not familial which is true in certain cases of constitutional hepatic dysfunction

PROGNOSIS

The general health of the patient who has constitutional hepatic dysfunction may remain excellent. Some patients may have no complaints and may be curious only about the jaundice (cases 1 and 2) In most cases the patient may and probably does, have other complaints

since otherwise he would not consult a physician. Such complaints are usually functional but may be of some other type. It is not certain that the fatigue and lack of vitality so frequently complained of are due to the condition.

As previously mentioned, the liver was normal in the one case in which biopsy has been performed.

TREATMENT

Whether treatment of constitutional hepatic dysfunction is indicated is questionable since it apparently does not affect the general health. Treatment such as is given in disease of the liver is disappointing and is not indicated. Cholecystectomy, choledochostomy and splenectomy have no influence on the course of the jaundice or on the functional complaints of the patient. Operations on the biliary tract are indicated only when bona fide disease of the gallbladder or calculous disease of gallbladder or ducts exists. Avoidance of preceipitating stresses such as overwork, fatigue and emotional and nervous stress may lessen the depth and the frequency with which increases in depth of jaundice occur.

COMMENT AND SUMMARY

Attention is again called to constitutional hepatic dysfunction, a condition in which jaundice is due to an inborn inadequacy of the hepatic cells, particularly with regard to excretion of bilirubin. Its sole clinical manifestation is acholuric jaundice. The jaundice may be latent or overt. The essential pathologic finding is an increase in serum bilirubin giving an indirect van den Bergh reaction. It is not due to hemolytic or true hepatic disease or disease of the biliary tract. The prognosis is excellent. Its recognition is important to prevent an erroneously serious prognosis and unwarranted medical and surgical treatment.

DIFFERENTIAL DIAGNOSIS OF NEPHRITIS

MELVIN W BINGER

THE disease commonly known as glomerulonephritis presents many varied and interesting problems in etiology, differential diagnosis and treatment, and it is the purpose of this paper to consider some of these problems

The disease, as first described by Richard Bright in 1827, was but vaguely understood and even now, more than one hundred years later, there are many aspects of the disease that are largely a matter of conjecture.

The disease presumably is due to an inflammation or toxic reaction of the capillary loops of the glomeruli, which is really an endocapillaritis and an involvement of a part of the vascular system. In the acute form it very frequently is associated with or follows infections of the upper part of the respiratory tract, tonsillitis, scarlet fever and other infectious processes. It has been determined by various investigators, and from our records at the Clinic, that in about 85 per cent of cases of acute glomerulonephritis the disease is attributable to infectious processes. It is hard to conceive that the organism causing the primary respiratory or other infection is transmitted by the blood and lodged in the kidneys, thus producing the glomerular changes. It is thought rather that toxins from the primary infection are the causative factor. The possibility of a virus exists and many investigators have considered an allergic reaction as the cause of the glomerular changes.

However, it is not my purpose to go into minute detail regarding the etiology and pathology and treatment of glomerulonephritis, but rather to consider the differential diagnosis of glomerulonephritis and suggest some of the common pitfalls in the diagnosis of this disease.

To make a diagnosis of glomerulonephritis solely on the presence of albumin and blood and casts in the urine is a hazardous procedure and may result in the wrong diagnosis, for many other disorders in the body may produce abnormal urinary findings.

Polycystic kidneys will produce the identical clinical picture of chronic glomerulonephritis and the differential diagnosis frequently is not easy, especially in cases in which the patients are obese and the concentration of blood urea is increased. The obesity makes palpation of the kidneys difficult and, if the value for the blood urea is more than 70 or 80 mg per 100 c c, intravenous urography is not a satisfactory method for outlining the kidneys as the iodine compound is not sufficiently concentrated to be visualized on the urogram. Retrograde pyelograms can be made, but always with some hazard. However, the size of the kidneys frequently can be outlined on the roentgenogram. If the value for the blood urea is normal or nearly normal,

excretory urography offers the best procedure for diagnosis. The outline of the distorted calices is quite typical in cases of polycystic kidney.

There may be a familial history of polycystic kidney which will give a lead for investigation. The course is more benign as a rule than that of chronic glomerular nephritis, and a high concentration of blood urea is better tolerated. The blood pressure will be elevated as in chronic glomerulonephritis with the usual diffuse vascular disease. Renitis develops as the disease progresses and cardiac degeneration and decompensation are common.

Chronic pyelonephritis is often mistaken for chronic glomerulonephritis, in the chronic, latent phase it may closely resemble the latter disease. In chronic pyelonephritis there is usually a history of recurrent infection of the urinary tract, with fever and chills pyuria and often hematuria and bacteria usually *Escherichia coli* frequently are found in the urine while bacteriuria is rarely seen in chronic glomerulonephritis. Intravenous urography usually will disclose distortion of the calices and pelvis of the kidneys owing to inflammatory changes. Often there is an associated cystitis which can be detected by cystoscopic examination. Stones often can be demonstrated in one or both kidneys and frequently will take the characteristics and form of pelvis and calices, forming the so-called staghorn stones. The infection may involve one or both kidneys. As the disease progresses there results a gradual renal impairment with all the characteristics of chronic glomerulonephritis namely, hypertension, uremia, vascular and cardiac changes and anemia.

If the disease is limited to one kidney the clinical picture will be the same, except that the remaining kidney will usually carry on the necessary excretion of nitrogenous matter unless or until resultant hypertension and vascular changes impair its function. If unilateral atrophic pyelonephritis is detected early and if the involved kidney is removed surgically the blood pressure may be restored to normal and the systemic progress of the disease may be checked. However if the disease has progressed sufficiently to cause serious vascular damage and serious impairment of the other kidney through vascular changes the results of removal of a unilateral atrophic kidney are not so spectacular and will do little or no good. Again, in this instance, intravenous urography retrograde pyelography and selective functional studies of the kidneys are important. The incidence of unilateral atrophic kidney resulting from chronic pyelonephritis is so common in cases of hypertension that the neurosurgeons insist on having excretory urograms made to rule out the presence of this condition before considering a splanchnic resection for the hypertension. I personally do not think that splanchnic resection should be considered in any case of hypertension until satisfactory intravenous urograms are made and unilateral or bilateral atrophic pyelonephritis has been definitely excluded as an etiologic factor. In fact, excretory urography is being

recognized more and more as an important diagnostic aid in cases of hypertension and chronic glomerulonephritis, to be sure that one is not dealing with atrophic pyelonephritis. I know of no situation that gives me more satisfaction than to find, and have removed, an atrophic kidney in a case in which the patient seemed doomed and, by this surgical procedure, restore a patient to health.

A condition that somewhat resembles atrophic pyelonephritis is *congenital hypoplastic or malformed kidney*, which may or may not produce hypertension and diffuse vascular changes. If hypertension is detected in a child, urologic studies should be made to rule out the presence of a unilateral hypoplastic kidney. If such a kidney is found, its removal should be seriously considered. This condition can and will produce the clinical picture of malignant hypertension.

Tuberculosis of the kidneys or of a single kidney may be confused with chronic glomerulonephritis, and, when pus and blood, as well as albumin, persistently occur in the urine, a centrifuged specimen of urine should be stained for *Mycobacterium tuberculosis*. If any doubt exists about the presence of this organism, guinea pigs should be inoculated. Excretory urography and cystoscopy are of immense diagnostic help. Fortunately, tuberculosis usually affects only one kidney and, if the involved kidney is removed, the chance of recovery is good. At present, chemotherapy does not seem to be of much value in this disease.

Hypernephroma of the kidney may produce albumin and blood in the urine. Usually, there are recurrences of gross blood in the urine. The malignant lesion may be far advanced before there is any clinical indication of its presence and I have seen cases of widespread metastasis in which the primary source was found by urologic studies. If the hypernephroma is discovered and nephrectomy done early, and if deep roentgen therapy is employed subsequently, the immediate outlook is favorable.

Adenomyosarcoma, or Wilms' tumor, in children may present the clinical picture of hypertension and nephritis. However, it is rarely encountered and the outlook is invariably poor. Urologic studies should be carried out in cases in which the presence of this tumor is suspected.

In the advanced stages of *essential hypertension* it is quite difficult or impossible to tell by the findings alone whether the primary condition was glomerulonephritis or essential hypertension. The albuminuria and sediment in the urine are similar in each disease. The impairment in renal function, the anemia, and the degree of hypertension are confusingly alike in the two diseases, and the end results, such as uremia, cardiac failure or cerebral vascular accident, occur with about equal frequency in the two diseases. In many instances, only the pathologist who examines the renal tissue can in any measure be certain as to which was the primary disease. However, there are certain

points in the history and physical examination that lend a clue. In chronic glomerulonephritis, there is often a history of acute nephritis which occurred after an infection of the upper part of the respiratory tract or other infection associated with fever. The acute glomerulonephritis is associated with edema, oliguria and gross hematuria. Early in the disease, the vascular changes and hypertension are less in evidence and the urinary abnormalities are more dominant. Albuminuric or vascular retinitis may or may not be present, and spasm and narrowing of the retinal arteries may be noted. In essential hypertension, the onset, course and symptoms may vary in intensity and character and the disease may not produce symptoms or may not be detected until it is well advanced. In many cases the disease is detected first at an insurance examination. Army medical examinations disclose many instances of essential hypertension in which the men were previously unaware of the disease. Nervousness, headache, insomnia, irritability, easy fatigability, dyspnea on exertion and, later failing vision, hematuria and albuminuria will be found. The retinas will usually show more sclerosis and retinitis than is seen in chronic glomerulonephritis. However in many cases of chronic glomerulonephritis the onset may be insidious and the disease may be far advanced and extensive secondary diffuse vascular disease may be present before the patient is aware that anything is wrong. It is in such cases in which the history is indefinite and the onset is insidious, that the differential diagnosis is difficult, and it is surprising how frequently one encounters this problem. However at this stage, the problem becomes chiefly academic and the treatment, course and prognosis are about the same in both diseases and from all practical aspects the two diseases become one and the same disease.

Subacute bacterial endocarditis can and frequently does present a clinical picture not unlike that of chronic glomerulonephritis and must be suspected in cases in which albuminuria and hematuria are present, particularly if there is evidence of mitral or aortic valvular disease or congenital cardiac anomaly such as patent intraventricular septal defect, patent ductus arteriosus, patent foramen ovale or coarctation of the aorta. Blood cultures should be made in suspected cases and if *Streptococcus viridans* is found, together with the cardiac findings, fever, petechia and general debility it is quite safe to presume that the renal findings are secondary to the primary infection in the blood stream. Space will not permit a detailed consideration of subacute bacterial endocarditis itself. In most cases the disease is due to *Streptococcus viridans* infection of a damaged heart valve, usually the mitral, or of congenital heart lesions. It is probable that the urinary picture is produced by emboli lodging in the glomeruli of the kidneys, resulting in abscess formation and destruction of renal substance. Hypertension is unusual in cases of subacute bacterial endocarditis and, when it is present, one must suspect pre existing vascular disease of ess

hypertension, chronic glomerulonephritis, or other diseases that produce hypertensive vascular disease. It is not common to see uremia in cases of uncomplicated subacute bacterial endocarditis. It is fairly common to see cases of subacute bacterial endocarditis in which repeated blood cultures are negative, and one should not be misled by negative blood cultures.

Periarteritis nodosum or diffuse endarteritis produces a myriad of symptoms and clinical findings that may be confused with those of chronic glomerulonephritis. There may be albumin, casts and erythrocytes in the urine, and hypertension and evidence of widespread cardiovascular disease. However, the severity and rapid progression of the clinical symptoms and findings are out of proportion to what one would expect in cases of chronic glomerulonephritis. Usually, the retinal findings are minimal and the evidence of cardiac damage is much more profound in periarteritis nodosum than it usually is in chronic glomerulonephritis. There, too, will usually be peripheral neuritis and pain and soreness in muscles and tenderness along certain arteries, which do not occur in cases of nephritis. If painful nodules along the arteries can be found, the evidence is rather in favor of periarteritis nodosum. A biopsy of a suspected nodule or region will frequently be the deciding clue in the diagnosis. Unfortunately, this disease presents such a widespread and atypical clinical picture that it usually goes unrecognized before death and, more frequently than not, the diagnosis is finally established by the pathologist at necropsy. The legion of clinical findings, the unusually rapid progress of the disease, the widespread organic involvement, the usual leukocytosis, fever, severe cardiac failure and cerebral involvement without definite clinical syndromes should lead one to suspect the presence of periarteritis nodosum.

Acute disseminated lupus erythematosus in many ways resembles periarteritis nodosum and subacute bacterial endocarditis and will produce a clinical picture that is easily confused with that of glomerulonephritis. It is thought by some investigators to be a closely related disease as far as the cause, clinical findings and course are concerned. It runs a subacute course with fever, progressive anemia and pronounced leukopenia. There may be pericarditis, arthritis and an erythematous and purpuric rash, usually involving the face but frequently also the extremities. Blood cultures are invariably negative. The protean nature of the clinical picture is thought by some investigators to be due to the widespread vascular involvement.

In *advanced pulmonary tuberculosis* and tuberculous involvement of other organs, the urinary findings, such as albuminuria, casts and hematuria, may be mistaken for those of chronic glomerulonephritis. These findings may result from the toxic effect on the kidneys or from tuberculous lesions of the kidneys. In the latter instance, *Mycobacterium tuberculosis* may be found in the urine. A widespread

amyloidosis may be present and can be readily detected by the Paunz test. Usually, careful general clinical studies including roentgenologic examination of the thorax, will be of help in establishing the correct diagnosis. There usually will not be the vascular involvement and hypertension that generally are seen in cases of chronic glomerulonephritis.

However in considering *amyloidosis* as a cause of albuminuria, it must be remembered that tuberculosis, although the most common, is not the only predisposing cause. There are cases of widespread amyloidosis in which a definite cause cannot be determined and because of the accompanying albuminuria, hypoproteinemia and edema the disease may be mistaken for a nephrotic stage of chronic glomerulonephritis. The downhill course of widespread amyloidosis, however, is much more progressively rapid than is nephrosis, which is relatively a mild disease, in comparison, and will run a fatal course in a few weeks or months. There will be evidence of severe damage of the liver with marked retention of dye, edema, ascites, usually of a chylous nature and rapidly failing renal function. The Paunz test will be strongly positive.

Amyloidosis also may be observed in many cases of large tumors, particularly those involving the bones and in syphilis, in multiple myeloma and in some cases of leukemia. In cases of atypical and rapidly declining nephrosis the Congo red test or the Paunz test should be done to be sure that one is not confronted with this disease.

In most cases of *multiple myeloma*, there is an unusual type of albuminuria which is known as Bence-Jones albuminuria, and, in cases of albuminuria, a test should be made for this type of protein. The test is quite simple and the result is characteristic. A white precipitate is formed when nitric acid is added to the urine, this precipitate disappears on boiling and reappears on cooling. In suspected cases, roentgenograms of the ribs, long bones and skull should be made to demonstrate whether the peculiar multiple lesions of bone are present. Frequently, sternal aspiration of bone marrow for microscopic study will reveal the myelomatous cells.

Bence-Jones protein however does not occur only in cases of multiple myeloma but may be found in some cases of leukemia, chloroma, myxedema, chondrosarcoma and malignant tumors of the gastrointestinal tract. In contrast to chronic glomerulonephritis and nephrosis, the serum proteins are usually elevated.

A rather rare disease that might at first consideration be confused with chronic glomerulonephritis is *hyperparathyroidism* due to adenoma of the parathyroid glands. Albuminuria, uremia, anemia and even hypertension may be observed. However, in about two-thirds of the cases there will be typical bone changes of osteoporosis and cystic degeneration of the bones. In some cases the disease may be confused with multiple myeloma. In most cases the value for the serum calcium

will be more than 11 mg per 100 c c and the value for the inorganic serum phosphorus will be less than 3 mg per 100 c c It is probable that in many of these cases the disease escapes diagnosis and is considered as nephritis or other systemic disease

In further consideration of the condition commonly known as *chronic lipid nephrosis*, one is confronted by the two schools of thought as to whether lipid nephrosis is a variety of chronic glomerulonephritis, or whether it is a degenerative disease of the kidneys and not a manifestation of chronic glomerulonephritis In my observations of cases of so-called lipid nephrosis, the disease eventually has progressed to typical chronic glomerulonephritis with uremia, hypertension and diffuse cardiovascular involvement Cases in which severe albuminuria, hypoproteinemia, and edema, hyperlipemia with normal or only moderately elevated blood pressure, and a normal concentration of blood urea are considered as chronic glomerulonephritis with the nephrotic syndrome The nephrotic syndrome apparently occurs in cases in which the nephritis is benign and in which so much albumin is lost through the urine over a long period of time that the concentration of serum protein is depleted to or below the critical level of 5 per cent, which results in a lowering of the colloidal osmotic pressure and of the blood, resulting in edema It is not clearly understood why there should be an increased permeability of the glomerular loops, conceding, of course, that the filtration of plasma proteins takes place through this element of the kidneys Neither is it clear why some patients with the nephrotic syndrome will have a normal blood pressure while others will have severe hypertension and vascular involvement It is thought to be due to the degree of impairment or unimpairment of blood flow through the kidney, which has been ably demonstrated by Goldblatt and other investigators

Lipemia is not peculiar to nephrosis alone, for it is frequently observed in cases of proved chronic glomerulonephritis

In *Hodgkin's disease* and *lymphosarcoma*, the clinical picture of nephritis is frequently observed There may be albumin, casts and erythrocytes in the urine, as well as renal failure, as evidenced by an increased concentration of blood urea Blood pressure may also be elevated and anemia may be present However, the generalized adenopathy, enlarged spleen and frequently the typical mediastinal widening are clues favoring the diagnosis of these diseases Frequently occurring attacks of fever of the Pels-Ebstein type may be noted Biopsy of a lymph node is advisable and frequently will establish the diagnosis It is thought the renal changes are due to infiltration of the kidneys by the malignant process However, in some cases only toxic changes were noted on microscopic studies Marked improvement is frequently noted after roentgen therapy Blood counts and smears are helpful in distinguishing Hodgkin's disease and lymphosarcoma from chronic leukemia, and the microscopic appearance of the

lymph nodes is typical of either disease. Usually splenomegaly is much more pronounced in leukemia than in lymphosarcoma and the spleen may attain an enormous size.

Whenever pus and blood are present in the urine, together with albumin, and particularly when the sediment is stringy and clotted, it is well to investigate the urethra, bladder and kidneys for some gross urologic lesion and not assume unequivocally that the patient has nephritis. Excretory urography and cystoscopic examination can easily disclose inflammatory lesions vesical stones, cystitis, ureteral and renal stones, vesical tumors, diverticuli of the bladder enlarged prostate with obstruction, secondary infection of the urinary tract and many other conditions that, on the basis of the urinalysis alone, would simulate nephritis.

In conclusion, I would say that the errors in diagnosis of renal disease and of any diseases which secondarily affect the renal system and produce abnormal urinary findings are made in assuming that the cause of the abnormal urinary findings is nephritis rather than keeping an open mind and considering other possibilities. Merely because most cases of albuminuria with microscopic hematuria, and casts together with hypertension and anemia are cases of nephritis does not indicate by any means that they all are. It is only by a careful analysis of the history physical examination and laboratory findings that one can hope to eliminate errors in diagnosis.

The importance of intravenous urography, cystoscopic and other urologic studies in cases of suspected nephritis should be emphasized.

CHRONIC CERVICITIS

MONTÉ C PIPER

CHRONIC cervicitis may include erosion of various types and degrees, chronic cellulitis and fibrosis, cysts, polyps, lacerations with infection, eversion and malignant changes

Symptoms resulting from chronic cervical involvement may be purely local or more extensively systemic. There is individual variation in the degree of distress. Rather extensive involvement of the cervix may produce surprisingly little discomfort in some cases and the diagnosis may be determined only by examination. In others the involvement may be mild but may seem to produce symptoms of an unwarranted severity.

Leukorrhea usually accompanies any degree of chronic cervicitis and is the most frequent finding. Pelvic weight or heaviness is often aggravated by fatigue and, if the paracervical ligaments are much involved, may result in actual pain. Dyspareunia may be complained of. Menstrual irregularities or abnormalities and increased dysmenorrhea sometimes accompany chronic involvement. Metrorrhagia should lead to careful search for any possible early malignant process. Sterility is sometimes corrected by eliminating cervical lesions.

More remote symptoms are most frequently complained of as urinary distress. The close proximity of the ureters and base of the bladder to the network of lymphatics, vessels and nerves surrounding the cervix explains the frequency of urinary complication. Both infections and neoplastic processes may readily invade the region of the bladder and the ureters by direct extension.

The history of a patient who has chronic cervicitis may be clarified by a frequent review of the salient points. Frankly discussing with the patient her ideas about her symptoms and explaining to her the findings and their probable significance will help to encourage her confidence and to manifest the physician's understanding of, and sympathy with her in, her problem. Some women hesitate to tell their story completely at first and it may happen that the patient will divulge her innermost fear only after treatments are completed and at the time of dismissal. Her chief anxieties may be summed up in the fear of having some loathsome disease, of development of a malignant lesion or of an inability to perform her normal sexual functions. The history should record duration, remissions and previous therapeutic attempts.

Pelvic heaviness or pain usually is responsive to the application of heat, to rest and to some of the more common analgesics. Back pain in the sacrolumbar region often accompanies cervicitis and its relief may follow elimination of the cervical involvement. It is fairly frequent for a patient to state that a chronic backache has been relieved in a

very few days after a cauterization of chronic cervical fibrosis containing multiple cysts

Records of about 1,000⁵ cases in which cervical cauterization had been performed from six to nine years previously were reviewed and questionnaires sent to the patients. Four hundred and forty had listed backache in their histories as one of their complaints. Of the patients who answered the questionnaire, 62 per cent reported the backache relieved while an additional 11 per cent said that the backache had been improved. It was not assumed that the treatment of the cervix was the only factor contributing to their relief but such a record seems significant.

The assumption that chronic cervicitis is a focus of infection in more remote regions is probably more speculative than proved but streptococci are often found on culture taken from cervical lesions. Some ocular conditions, such as episcleritis, have responded favorably after correction of cervicitis and in cases of infectious rheumatism the cervix should be examined as a possible source.¹ Certain types of renal infection seem likewise to lose their tendency to exacerbations after the chronic cervical involvement has been healed. Some authors have classed the cervix as being as important as the tonsils and teeth as a source of infective processes.

Chronic cervicitis is most frequently inaugurated at childbirth and thus occurs in the third or fourth decade of life, which is perhaps the age of greatest stress and strain to the mother. The psychic effect on her personality when she is relieved of her nagging pelvic distress is gratifying.

The etiologic production of cervicitis is commonly attributed to infection though there are cases of erosion of the cervix in which it is difficult to discover an infection as a preceding involvement.

Infective processes are usually superimposed on some form of trauma such as that produced during childbirth with the bruising and lacerations, in some previous instrumentation or as the result of an acute infection overwhelming the defense mechanisms. There is a resulting residue in the endocervical glands and tissues of the portio vaginalis and adjacent structures. The chronic infective organism is usually a streptococcus but its invasion may have been made possible by an acute onslaught in which organisms such as *Neisseria gonorrhoeae*, *Escherichia coli*, some types of staphylococci, diphtheroids, *Mycobacterium tuberculosis* and other less common bacteria were producers of the initial acute process. The foregoing acute infection may have destroyed the defense barriers of the tissues and that may have allowed the invasion of the streptococci. Racial and environmental characteristics may vary the incidence of the less frequent organisms but the streptococcus seems to be the offender which persists after the primary acute inflammation has subsided.

A rather violent epithelial irritation may be set in action by parasitic

organisms such as *Trichomonas vaginalis*, *Monilia albicans* and some others and thus prepare a means by which streptococci gain access to deeper tissue and institute a more extensive involvement than is usually observed in cases of parasitic vaginitis. It is not known that the foregoing parasites of the vagina have invasive properties in themselves but it is believed that they act in symbiosis with pathogenic bacteria and allow of deeper chronic involvement.

Defensive processes against infection in the cervix are manifested by an intricate anatomic structure of the endocervix and by the outflow of alkaline mucus, which is then liquefied and acidified in the vaginal vault by the action of the vaginal fluids. A mild chemical reaction thus occurs about the portio vaginalis. This process varies in different individuals and is influenced by their degree of natural immunity and general condition of bodily health. It is further varied by the hormonal influence on the vaginal epithelium in the quantity of glycogen available for conversion into lactic acid in the vagina, by the outflow of menstrual fluids and no doubt by other influences such as psychic stimuli not well understood.

Examination of the patient in anticipation of treatment for any condition is benefited by a general systemic review. A good physical examination is as essential in dealing with pelvic conditions as in dealing with conditions in any other portion of the body. Leukorrhea being the most frequent symptom of cervicitis, the nature of the discharge should be sought and its origin ascertained. Cultures and smears are advisable to determine the presence of *Neisseria gonorrhoeae*, *Trichomonas vaginalis* or *Monilia albicans* and the character of the pus and of the desquamated epithelial cells. There are likely to be a suggestive odor and consistency to secretions associated with the foregoing types of infection and gonorrheal infection is likely to reveal involvement of Bartholin's and Skene's glands. Malignant processes have an odor of necrotic tissue and secretions may be watery and blood stained.

Palpation should acquaint the examiner with the tone of the tissues of the vagina and supportive ligaments and the position, size and consistency of the cervix, the fundus and the adnexae. Nabothian cysts may possibly be more readily palpated than visualized. Palpation through the rectum is advisable if possible, as the adjacent cervical tissues and uterosacral and broad ligaments are often more accurately palpable by rectal than by vaginal examination.

Inspection of the cervix requires that the patient be in a comfortable position. If the vagina is unduly sensitive, a mild local anesthetic may be used. A good light is essential. Evidences of lacerations, edema, polyps, erosions, cysts, bleeding points and ulcerations are looked for. A small cold light introduced into the cervical canal may reveal by translucence deeply buried cysts which would otherwise be unsuspected. Gently pressing on the surface of the portio vaginalis with a blunt tipped probe may reveal irregularities of resistance and spongy

regions from which one may desire to remove tissue for biopsy. Perhaps tissue should be removed for biopsy from all lesions of the cervix but certainly from papillary or polypoid regions regions which tend to bleed after slight trauma, an obvious ulcer, areas of leukoplakia or areas which are velvety and allow the probe to sink readily into the substance of tissue, a specimen should be removed and examined by a pathologist. A diffuse milky gray color of the surface of an erosion and superficial telangiectatic patches indicate advisable fields for biopsy. It is far wiser to have a negative pathologic report than to have destroyed by cautery a region which may have been the site of an early malignant lesion without having taken a specimen for biopsy.

An erosion of the uterine cervix is an interesting and fairly common lesion. The usually accepted theory of the formation of erosions is that the squamous cell epithelium of the portio vaginalis becomes macerated by infectious debris and fluids and that cells of columnar type progress out from the endocervix and replace with a columnar celled covering the epithelium so macerated. Such an erosion is usually rather sharply limited on its outer border and its columnar celled surface is confluent with the covering layer of the endocervix. Yet the typical racemose glands of the endocervix are not always produced in the erosion and there is some question whether the nabothian cysts seen in the region of erosion may not be inclusion cysts produced by infolding of this abnormal tissue growth. Certainly many erosions are seen in which evidence of previous infection does not appear and the previously mentioned stage of maceration of the squamous layer is seldom encountered. Some erosions seem to grow by piling up of layers of cells, so that they may appear crowded into folds or tufts or into minute papillae so closely packed as to resemble the surface of clipped velvet. Various manifestations of infection and cyst formation do appear in association with some erosions but there are other erosions which seem to be an uncomplicated metaplasia, in which cells of columnar type have replaced squamous layers over a limited area. The basement cells, which formerly produced squamous cells for some reason produce columnar cells. Why should such metaplasia occur? Is the area of metaplasia an extension of columnar cells from the endocervix or are these columnar cells formed by the existing basement cells?

The hypothesis of cellular adaptation to an unfavorable environment⁷ allows a speculative inference that a similar process may occur in the production of an erosion of the cervix.

The environment of the cervix is subjected to various influences, such as the hormonal variation of the host. The chemical reaction mentioned previously varies in its intensity with fluids discharged from the upper part of the genital tract and these fluids are derived from the endometrium. The stages of the menstrual cycle produce repeated rhythmical variations. Processes of metaplasia have been re-

ported^{2 3} from such situations as the bronchus, gallbladder, stomach, pharynx, prostate and anus and over the exposed surface of a long-standing chronic inversion of the uterus

When the process of metaplasia occurs on the portio vaginalis of the cervix, the basal cells of the mucosa, which form the reproductive or functioning layer, seem to alter their product from the supposedly natural protective squamous type of epithelium to a more secretory glandular-like columnar epithelium and a so-called erosion is produced. The basal cells of both the columnar and the squamous types of tissues of the portio vaginalis are said to appear to be similar histologically

If such a process does occur and produce an erosion as a result of cellular adaptation to unfavorable environment, could not a hypothesis go further and assume that cellular adaptation to unfavorable environment of frequent recurrence might proceed to the production of the disorderly groups of cell arrangement found in "carcinoma in situ" or "noninvasive epithelioma"? If those tumors are truly malignant tissue, and evidence^{4, 8} seems to be accumulating that they may develop into the more common examples of malignant process, they offer an earlier step in diagnosis than the commonly accepted stage 1 carcinomas of the cervix. Carcinoma in situ is not diagnosed except by the pathologist and no doubt many such carcinomas have been destroyed by cervical cautery when a specimen for biopsy was not obtained. Some reports indicate reduction in frequency of primary carcinoma of the cervix since cauterization has become more prevalent

Treatment of chronic cervicitis is aimed at eradication of the lesion. Actual destruction by some form of heat such as electric hot wire cautery is more commonly employed than surgical removal at the present time

Cauterization by nasal tip cautery is a convenient process and is performed under direct visualization. It may be an office procedure and the patient may remain ambulatory. Other processes of actual destruction of diseased tissue may be equally efficacious and may be preferred by some but actual cautery has the advantage of simplicity of equipment, of visual control of extent and of minimal complications. Burning should be done slowly with a dull red, rather than a bright yellow, wire loop and should extend to a depth just through the mucosa. The lines should be spaced closely enough together so that radiant heat coagulates the intervening tissue and turns it ash-white. Cysts are evacuated by cautery puncture and their lining membrane is coagulated. If severed small vessels tend to spurt or ooze, they are nearly always controlled with the cautery by holding the glowing tip against the bleeding point. Sometimes the bleeding is effectually stopped by cauterizing deeper in an adjacent line, thus reaching the vessel in deeper tissue. When the cervix is considerably thickened and the lips are everted and contain deeply buried cysts, the cautery incisions may

be deeper and extend farther into the substance peripherally, so that the shrinkage which results tends to restore the cervix to a more normal size.

Whether or not the endocervix should be cauterized depends on its involvement. In cases of simple superficial erosion there seems no good reason for destroying the endocervix and healing is completed in a shorter period if only a surface cautery is required. When the endocervix is involved and requires cauterization it should be quite thoroughly treated and the cautery lines from the endocervix should cut deeply at the os and extend to the periphery of the area to be cauterized on the portio vaginalis. The resulting fibrosis tends to result in an open os and is less likely to result in stenosis. The endocervix is not usually visualizable. When it is extensively involved, the procedure of conization may be preferable. However, this should be an operating room process and after conization there seems a greater incidence of subsequent hemorrhage and the need of frequent observation because of the tendency to stenosis.

After actual cauterization there occurs a heavy slough, which softens and produces a foul leukorrhea for four to six days but which has usually cleared off in about ten days. During the healing stage it is permissible to wipe the cervix with a mild antiseptic on a cotton applicator, a procedure which will help to prevent some of the bad odor and at the same time permit inspection of the cauterized area for small adherent clots of blood or bleeding points. These clots may be wiped away and an astringent solution applied. Healing and a new surface have organized in four to six weeks but subsequent involution may not be completed for perhaps six months. Examination by palpation and inspection seems worth while at a three months' and again at a six months' interval, particularly to ascertain whether all cysts have been destroyed and whether the lesion is completely healed and to determine the amount of involution ultimately obtained by the procedure. Complications are usually not severe. Postcautery bleeding during the sloughing off of the eschar may require attention for a few days and many minor processes are utilized to check bleeding of the areas. In some instances a packing of iodoform gauze may be required. When it is employed, it should be left in place for forty-eight hours, so that the removal of the gauze may not again open the bleeding vessel. Pelvic ache may be aggravated for a few days in some cases and occasionally an unsuspected subacute inflammation of the adjacent pelvic structures will flare up so as to produce febrile reaction. However, such reactions usually subside promptly. Urinary complications are at times temporarily aggravated. A tendency to cervical stenosis of the os occurs in some cases and may respond simply to dilatation. If it repeatedly recurs, an enlargement of the opening may be effected by a crossed incision through the os by means of the cautery wire.

SUMMARY

A chronically diseased cervix may be the source of either local or more systemic symptoms. The causation of cervical erosions is an interesting field of speculation. The suggestion is offered that these erosions may perhaps be a manifestation of metaplasia resulting from cellular adaptation to unfavorable environment and that so-called carcinoma in situ may be a further step in such a metaplasia. The foregoing is only suggested as a speculation, for proof of such process seems lacking at the present time. However, erosions and other cervical lesions justify the taking of a specimen for pathologic analysis and the correction of lesions of chronic cervicitis seems to have assisted in a reduction of the occurrence of cervical malignant disease.

CERTAIN CONDITIONS OF THE FEMALE URETHRA

EDWARD N. COOK AND JANE L. HODGSON

The purpose of this discussion is to review certain conditions of the female urethra from the standpoint of etiologic factors, symptoms, diagnosis and treatment. Such a discussion presupposes a thorough knowledge of the anatomy of this part of the body.

The female urethra is a short tubular structure, 3 to 5 cm. in length, extending from the bladder to the vestibule. In multiparas it is usually shorter than this. The external urethral meatus, which may be slitlike or may resemble an inverted Y, is usually the narrowest portion of the urethral canal. The urethral wall has a mucous, submucous and muscular coat. The epithelium lining the canal is of the stratified, squamous type except near the bladder where it becomes transitional in type, similar to that of the bladder. There are many small tubular glands in the proximal one third of the urethra and a few lesser ones in the outer third. On each side of the floor of the urethra just within the external meatus are the two openings of Skene's glands. In some instances the orifices of these glands may be in the vestibule adjacent to the external meatus. The submucosa is a layer of loose areolar tissue with some elastic fibers and a network of venous spaces. The muscular coat is composed of two layers, an inner longitudinal layer and an outer circular layer. The inner portion of the circular layer at the vesical outlet forms the involuntary sphincter of the bladder. The true voluntary sphincter is a layer of striated muscle fibers arising between the two layers of the triangular ligament, surrounding completely the urethra and extending proximally to the vesical outlet.

Since the urethral channel in the female passes directly from the bladder to the outside, it has a markedly inferior defense against ascending infection as compared with the urethral channel in the male. The external urethral meatus is in constant contact with vestibular and vaginal secretions and consequently there is the ever present possibility of organisms entering the urethra and setting up a distressing condition. The majority of infections of the urethra in the female are of this type.

Proper evaluation of the patient's complaint is of primary importance. At the Clinic patients are frequently encountered who have been taking a urinary antiseptic because of urinary symptoms and the finding of pus cells in a specimen of voided urine. No benefit has been derived from this treatment and further examination of a specimen of catheterized urine reveals no cellular elements. Such a situation should indicate the need for urethroscopic and cystoscopic investigation since proper evaluation of the patient's distress can be made only by this means.

URETHRITIS

One of the most common maladies of the female is inflammation of the urethra. This lesion frequently is found in women more than forty years of age. The classic experiment of Winsbury White did much to explain the frequent association of urethritis and trigonitis with endocervicitis, and also the fact that urethritis frequently accompanies monilial, trichomonal, gonorrheal, puerperal and postabortive infections. White demonstrated the relation between the cervix of the uterus in guinea pigs and the trigone of the bladder. He injected India ink into the cervix uteri and later found the dye in the lymph spaces where the bladder and vagina are in intimate contact.

The most common symptoms of urethritis are frequency and burning on urination. Urgency and dysuria also may be present. In the more severe cases tenesmus is noted. These irritative phenomena usually are aggravated during micturition and many times reach their greatest severity immediately after the act is completed. Hematuria is not common but may be present. If symptoms of external irritation are present, they usually are caused by associated meatitis. Dyspareunia occasionally is encountered, particularly if there is an associated urethral diverticulum. Any or all of these symptoms may be present in the various types of urethral inflammation.

The remainder of the discussion of urethritis deals with two forms of this condition, namely, simple urethritis and senile urethritis.

Simple Urethritis.—This form of urethritis, which is by far the more common, can be divided into granular and cicatricial types with or without associated inflammatory tags. On urethroscopic examination of the granular type the mucosa is raised, reddened and has a granular appearance in scattered regions or throughout the whole urethra. Purulent secretion seldom is encountered. Frequently there is diffuse tightness of varying degree to the passage of the instrument along the canal. This may exist alone or in association with the granular change. At times a cicatricial process may have advanced to such a degree that there is a true stricture with symptoms of obstruction to the passage of urine as well as the objective findings of residual urine and trabeculation of the bladder.

In many cases of granular and cicatricial urethritis there are localized regions of mucosal proliferation, particularly at the vesical neck, which are referred to as inflammatory tags. These swollen reddened regions in themselves cause no particular difficulty and are only another manifestation of the granular change in the mucosa.

In the treatment of simple urethritis, the use of irritating medicines, frequent instrumentation and all forms of cautery should be kept at a minimum. In the granular type, the use of a mild astringent such as argyrol, 5 per cent, or protargol, 1 per cent, applied once daily for a week on an applicator of cotton and left in place for five to ten minutes usually is of benefit. Warm sitz baths also should be taken daily.

If there is associated cicatricial change, the urethra should be dilated every two or three days until it readily admits a 30 F or 32 F sound. Fulguration of the urethra in the female is of little value and extensive treatment of this type often results in extreme inflammation and cicatrization.

At the Clinic this simple and mild type of treatment has proved most successful. It is important to emphasize to patients the benignity of the lesion and also the harm that can result from overtreatment. A proper understanding by the patient of her trouble will help her to tolerate the occasional mild recurrences.

Senile Urethritis.—Since senile urethritis is comparatively rare, it is frequently overlooked. The symptoms may be severe and yet the signs of urethritis may be mild. The urethral mucosa may present a thinned out and somewhat reddened appearance similar to that of the mucosa of the vagina when senile vaginitis is present. The onset of the urinary symptoms and the onset of the menopause usually are simultaneous. The administration of estrogens has been of great value.

PROLAPSE OF URETHRAL MUCOSA

In prolapse of the urethral mucosa there is eversion of the mucous membrane of the urethra through the meatus, resulting in a red, congested tumor-like mass at the external meatus. The condition is important because it is frequently confused with caruncle of the urethra, which will be discussed in the next paragraph. Prolapse of the urethral mucosa probably is due to certain cicatricial changes which result from long-standing chronic inflammation of the urethra and meatus. The prolapsed region may bleed easily and is frequently the site of associated meatitis. Local tenderness and burning on urination often are noted. Treatment is essentially the same as for granular urethritis, with dilatation of the urethra if indicated and the use of mild astringent ointments locally if the meatus is inflamed.

CARUNCLE

Caruncle, which is a mucous polyp usually arising from the posterior aspect of the urethral meatus, frequently is confused with prolapse of the urethral mucosa, as previously mentioned. It is usually single but may be multiple. As a rule, a caruncle is exquisitely tender, fragile and bleeds easily, and at times the lesion is incapacitating. It may be papillomatous or angiomatous depending on its histologic structure. Treatment is best carried out by excision either by clamp or by scissors and cauterization of the base by scarring with mercuric nitrate, according to the method of Crenshaw. O'Connor advised electric desiccation with a needle electrode, care being taken to coagulate the entire base of the caruncle without destroying the surrounding tissue.

URETHRAL DIVERTICULUM

Many causes have been recorded as being responsible for urethral diverticulum. This condition probably is acquired and may arise from infected periurethral glands. The symptoms are much the same as those encountered in cases of simple urethritis but frequently are more severe. Occasionally, swelling may be palpated in the anterior vaginal wall which on pressure produces a discharge from the urethral orifice. Pain on walking and dyspareunia occasionally are noted.

The diagnosis is made by demonstration of the pocket with an opaque medium. On cystoscopic examination one or more minute scarred openings may be seen in the floor of the urethra. If possible, a soft 4 F ureteral catheter is passed into the opening and coiled in the pocket. Opaque medium then is injected and a roentgenogram made. At times a mass in the anterior vaginal wall may be palpated. The urethral diverticulum occasionally may contain calcareous material.

The treatment is surgical. Local therapy in the form of strong astringent solutions or fulguration are only rarely of value. Surgical excision of the pocket through a vaginal approach, with careful closure of the urethral opening and repair of the urethral floor usually are necessary to relieve this distressing complaint.

REAL VERSUS SUPPOSED DISTURBANCES OF THE ENDOCRINE GLANDS

EDWARD H RYNEARSON

MANY physicians have had the opportunity to observe "endocrinology" almost from its beginning to its present state. The term "endocrinology" was applied to the study of the endocrine glands at a time when not all of the glands were recognized and when few of their functions were known. These physicians can remember when tablets of whole pancreas were prescribed for diabetes, when epinephrine was the treatment for Addison's disease and when ovarian residue was prescribed for the menopause. They have lived to see the recognition of more of these glands and the delineation of many of their functions. Yet endocrinology still is not a science and still is but a part, though a most intriguing part, of internal medicine.

As knowledge has increased, better definitions of certain disturbances of the endocrine glands have been possible. What are some of these?

THE POSTERIOR LOBE OF THE PITUITARY

This small amount of tissue produces two hormones. One is pitocin which stimulates the contraction of the uterus and is useful for certain obstetric conditions. The other is pitressin which induces peripheral vasoconstriction and stimulates smooth muscle. It has an important antidiuretic effect. No known syndrome has been established that is due to the overproduction of the hormones of the posterior pituitary.

Diabetes insipidus is caused by the underproduction of the posterior pituitary and the consequent absence or decrease of its antidiuretic effect on body tissues. The many possible etiologic factors are described in the excellent observations of Ranson and his associates.⁶ The symptoms of diabetes insipidus need no review. The treatment consists in the replacement of pitressin by one of three methods. The first is the use of pitressin in aqueous solution, the disadvantages of which are the expense, the annoyance of multiple hypodermic injections and the sometimes unpleasant side effects due to stimulation of smooth muscle. The second method, the use of pitressin tannate in oil, has the advantage over the first method of delayed absorption which necessitates fewer injections. The third, and method of choice, is the nasal insufflation of powdered whole posterior lobe. Almost never does a patient find this method irritating to the nasal membranes and the patient prefers it to the other two methods because of its ease of administration, its relative inexpensiveness and the absence of unpleasant side effects. Few patients need more than an application of powder in the morning and evening and they learn to measure on the end of a

small blade or nail file the amount which is to be snuffed or blown into the nares

Some patients who are "supposed" to have diabetes insipidus, in reality, are only nervous water drinkers. For one reason or another their habit of drinking large quantities of water or other fluids has developed. Only occasionally do they drink as much as the patient who has diabetes insipidus and practically never do they drink as much during the night. A patient who has diabetes insipidus may drink as much or more during the night as during the day. Such a patient may arise eight or ten times during the night to urinate and drink, the nervous water drinker rarely presents this history. The concentration test,⁴ easily performed, determines the diagnosis since the nervous patient concentrates urine normally, but the patient who has untreated diabetes insipidus cannot concentrate urine to above a specific gravity of more than 1.010.

THE ANTERIOR LOBE OF THE PITUITARY

This small gland has only two types of secreting cells, the acidophil cells and the basophil cells. There is no known secretion from the chromophobe cells. Physicians are asked to believe that these two types of cells are capable of secreting a large number of distinct hormones, such as one or more gonadotropic hormones and hormones essential for growth, the function of all the other endocrine glands and the utilization of food and water. There is no question about the importance of this gland in the growth, maturation and function of the body, there is serious doubt as to whether this is accomplished through the production of so many distinct hormones. These matters have been summarized completely in another publication.²

Clinically, there are not many recognized disturbances of this gland. Underfunction, underdevelopment or removal prior to puberty produces the clinical picture of *dwarfism* or *infantilism*, underfunction or removal after puberty results in the syndrome of *hypopituitarism*. There are, of course, many variations but the condition which follows the surgical removal of the gland is well known to all physicians. Some have seen one of the rare cases of *Simmonds'* or *Sheehan's syndrome* which follows the destruction of the anterior pituitary gland. These occur most often in women who have had a severe hemorrhage or shock after childbirth. All have seen the clinical picture which follows the destruction of the pituitary due to adenoma of the chromophobe cells. These typical examples are mentioned because often the diagnosis of pituitary insufficiency is made on insufficient data. Many fat boys have the clinical picture known as *Frohlich's syndrome* but few have any organic disease of the pituitary, most patients whose condition is diagnosed as *Simmonds'* disease are really suffering from *anorexia nervosa* and certainly few undersized individuals are suffering from pituitary insufficiency.

Unfortunately, the treatment of pituitary insufficiency is unsatisfactory. A recent review of the literature¹¹ revealed that the clinical use of the anterior pituitary hormones has been disappointing. Since commercial growth hormones have not helped in the treatment of true pituitary dwarfism why should anyone expect them to prove of value in the treatment of the undersized individual who is usually the child of small parents. There are two main objections to the use of anterior pituitary extracts (1) They are rarely and only temporarily effective and (2) there is good evidence that administration of these hormones results in the production of antihormones which render the treatment ineffective. This does not mean that the careful, critical use of such hormones should be stopped entirely but their widespread use does not seem justified by evidence. Some patients have been helped by the use of the extracts of those glands which are nonfunctioning as a secondary result of pituitary failure. Thyroid, adrenal and male or female sex hormones are sometimes helpful but often results of their use are disappointing. Gonadotropic hormones obtained from the urine of pregnant women (chorionic gonadotropins) or from the serum of pregnant mares (equine gonadotropins) are pituitary-like in character and have had more extensive clinical use than anterior pituitary hormones. Their use for males, particularly in the treatment of undescended testes, has been reported by many observers. The administration of either or both in the treatment of women likewise has been reported frequently.

Overfunction of the anterior pituitary gland produces a syndrome which depends on the age of the individual and the type of hormone being produced in excess. Thus an excess of growth hormone, supplied before ossification is complete produces *gigantism*, after this, it produces *acromegaly*. Many patients who have an excess of the growth hormone can be treated successfully by roentgen rays to the pituitary. If changes in the visual fields are present and progressive, the surgical removal of the gland is advisable.

But again, a true glandular disturbance is not present in every "supposed" case. The sixteen year old girl who is 5 feet 10 inches (177.8 cm.) tall and well proportioned is probably entirely normal and certainly needs help only in making a philosophical adjustment to her height. Many women are supposed to have a basophilic adenoma simply because of obesity and hirsutism. There are thousands of fat, hairy women with irregularity or absence of menses but not one in a thousand has true Cushing's syndrome. In the light of our present knowledge the other 999 need a frank discussion, instruction concerning a regimen for reduction of weight and advice concerning the cosmetic treatment for the excess hair. Many women who have had help in losing excess weight and disfiguring hair are again happy members of society.

*Pituitary basophilism*⁸ (Cushing's syndrome) is rare and serious. If

it occurs in a girl prior to puberty, she will undergo premature maturity, may menstruate, develop large breasts, and so forth, if it affects a woman, amenorrhea and masculinizing changes follow. In both a peculiar obesity will involve the trunk with the Buffalo hump across the shoulders and the arms and legs are relatively thin. The skin is often plethoric and covered with acne and hair. Wide purplish striae are present. Examination shows variations of hypertension, osteoporosis, polycythemia, glycosuria, hyperglycemia and elevation of the basal metabolic rate. The picture is comparable in many respects to that produced by a tumor of the adrenal cortex or an arrhenoblastoma of the ovary. Once these conditions have been excluded, the only treatment is roentgen therapy to the pituitary.

After such treatment, many months pass before any improvement may result and only too often the whole sad picture may recur after it has seemed to disappear completely. The seriousness of this condition is an important reason for careful application of the term, records are available of patients who have committed suicide after receiving this diagnosis.

THE THYROID

Only a small fraction of the thyroid extract which is manufactured commercially is used for the treatment of *myxedema*, most of it is used for conditions which are "supposed" to be associated with a lack of this hormone. Myxedema responds excellently to administration of thyroid extracts. Because myxedema is a clear-cut entity caused by the lack of a single hormone, the administration of a small amount of thyroid extract completely controls the condition. I have not seen any patient with myxedema who required more than 2 grains (0.13 gm) of desiccated thyroid extract per day and the addition or subtraction of even $\frac{1}{4}$ grain (0.016 gm) is reflected in the patient's condition and basal metabolic rate. I have never seen a patient with uncomplicated myxedema who could not tolerate the use of thyroid extract, although many of these patients have unpleasant symptoms, such as generalized aches and pains, for the first few weeks of treatment. Very rarely thyroid extract cannot be administered because of the coexistence of a serious condition, such as severe angina pectoris.

Contrast this with all the patients with "supposed" thyroid deficiency. One such patient has a low basal metabolic rate (-16 per cent) and she complains of being chronically tired. "I feel low all the time," she states. Her basal metabolic rate is not all that is low, so may be her hemoglobin, blood count, blood pressure and gastric acids. Many organs may be low including a "dropped stomach," "dropped colon," "dropped kidneys" and a retroverted uterus. Yet the treatment that is most likely to be tried first is administration of thyroid extract. After she has taken 5 grains (0.3 gm) daily for five weeks her basal metabolic rate is found to have risen only to -14 per cent.

This exaggerated hypothetical case can be reproduced, with variations, in the experience of all physicians. Nothing that can be said or done will affect this abuse. Use of thyroid extract should not be limited to the treatment of myxedema for often it helps other conditions and it is often only by trial that this can be determined. Often it helps in the management of obstetric and gynecologic cases in which the indications for its use are not too well defined. However, if its use is ineffective, it should be stopped. The abuse of thyroid extract in the treatment of obesity is well recognized. To date, 48 grains (3.2 gm.) of desiccated thyroid extract daily is the largest dose that I have found any patient taking.

The syndromes of overfunction of the thyroid are also easily recognized. All physicians can make a mistake in diagnosis but there is little general abuse of the diagnosis of *hyperthyroidism*. The use of strong solution of iodine followed by thyroidectomy constitutes most satisfactory treatment. The occasional recurrence and the still more infrequent development of severe postoperative complications of the eyes remain the chief discouragements. Much interest has followed the publication by Astwood² of treatment with chemotherapeutic agents. Some observers are of the opinion that thiouracil or an allied substance eventually may replace the use of surgical procedures and they may. At present most observers are finding their use an excellent method for the preoperative care of certain patients and for the sole treatment of a few patients for whom operation cannot be advised.

THE PARATHYROID GLANDS

A separate article in this number deals with hyperparathyroidism and this condition will not be discussed here.

Parathyroid insufficiency occasionally occurs spontaneously, but far more frequently follows the injury to, or removal of, the parathyroid glands at the time of thyroidectomy. After this accident or spontaneously the level of calcium in the blood decreases and that of phosphorus increases. The symptoms which are well known consist of nervous excitability with positive Chvostek's and Trousseau's signs, muscular spasms, particularly of the extremities, and numbness and tingling, particularly about the lips. Usually the condition is easily recognized, readily confirmed and rapidly responds to treatment. The treatment consists in increasing the concentration of calcium in the blood. Parathyroid hormone is rarely used because it is expensive and may be dangerous if its uncontrolled use is prolonged. Calcium chloride or calcium gluconate can be given parenterally if the need is urgent. In most cases the condition can be controlled by the need and inexpensive use of calcium by mouth with vitamin D to aid in its absorption in the intestine. A teaspoonful of calcium lactate or calcium gluconate (4 gm.) administered every 4 or 6 hours for more frequently (if necessary) will control parathyroid insufficiency in almost every case.

If calcium lactate is used, it should be stirred in boiling water until a clear solution results, since it is poorly absorbed if it is not in solution. Calcium tablets are much less effective. Vitamin D can be given by mouth twice daily.

Two other substances which should be mentioned are calciferol (vitamin D₂) and dihydrotachysterol (A T 10). These are crystalline products obtained by the irradiation of ergosterol. They are effective when given by mouth and are extremely potent. As in the use of the parathyroid hormone, care should be exercised to avoid overdosage.

THE PANCREAS

The chief endocrine function of the pancreas is, of course, the production of insulin. The role of its other endocrine and excretory products will not be discussed in this paper. *Diabetes mellitus* usually is recognized easily and the treatment with diet and some type of insulin is well understood. The only condition which may be confused with diabetes mellitus which I will mention is that of the patient whose urine shows some reducing substance and whose blood sugar is normal. If a sugar tolerance test is performed and the result indicates decreased tolerance for sugar, then the diagnosis of diabetes mellitus appears on the patient's record. From that moment on it will be difficult, and sometimes impossible, for the patient to obtain life insurance, if insurance is issued, it is with increased premiums. One such patient returned to the Clinic and the results of repeated sugar tolerance tests were normal. Life insurance finally was granted. The sugar tolerance test is not a specific test for the presence or absence of diabetes. It is affected by absorption, by obesity, by the patient's diet, by many disturbances of the liver and muscles and by the various endocrine glands. Even when the test on a thin person who has been on a high carbohydrate regimen is positive the interpretation may be questioned. In cases of the type under consideration in which the level of the blood sugar is normal, the patient can be as well protected by discussing the need for further observation as by doing a sugar tolerance test. This test is of much more importance when it gives a negative result than when the result is positive. When the result is questionably positive the diagnosis should be deferred.

In contrast to definite diabetes mellitus is *hyperinsulinism*. The first proved instance of this disease was reported in 1927¹ and the total number of proved cases is probably less than 200, yet the literature contains reference to thousands of supposed cases. A patient who has proved hyperinsulinism usually has clear-cut symptoms of a severe insulin reaction occurring only when he is fasting or has been exercising. His blood sugar readings at such times are very low. He obtains prompt relief from the administration of carbohydrate and all symptoms disappear completely after the successful removal of an insulin producing adenoma of the pancreas. Unfortunately, the term⁷ "hyper-

insulinism" is applied to the condition of many patients whose symptoms are bizarre, who do not have low values for fasting blood sugar, who obtain questionable relief from the administration of carbohydrate, whose sugar tolerance curves may be flat and who usually can better be described as suffering from neurocirculatory asthenia or chronic nervous exhaustion. If the criteria as defined by Whipple¹³ are followed in making the diagnosis, confusion in the use of the term will be less severe.

THE SEX GLANDS

There is little difficulty in the diagnosis of conditions arising from overfunction of the sex glands. These conditions are the result of tumors or hyperplasia of the ovaries or testes. The most common one is an *arrhenoblastoma of the ovary* which produces the clinical picture comparable to a tumor or hyperplasia of the basophilic cells of the pituitary (Cushing's syndrome) or a tumor of the adrenal cortex.

There is much more difficulty in making the diagnosis of underfunction. From the earliest days of medical history there are references to the *female menopause* and it is only within recent years that successful treatment of the accompanying symptoms has been possible. New diagnostic aids are available such as assays of the hormones in the urine (and blood) and study of the vaginal and endometrial cells. Physicians are no longer entirely reliant on the patient's story for diagnosis. It will be years, if ever, before treatment is standardized and each physician is partial to his own plan for the use of natural or synthetic estrogens in the treatment of the menopause. Other endocrine products, including testosterone propionate, thyroid, pituitary and pituitary-like hormones, are being used.

The references in medical literature to the *male menopause* have increased tremendously since testosterone propionate was made available. If the male menopause is really so common, why was it not more discussed in the past? If, as is sometimes stated, it is as common as the female menopause, why has it been mentioned so rarely? No one questions its identity, many question its incidence. When male hormone is administered in questionable cases and good results follow, the conclusion is that the treatment confirms the suspicion. Yet critical studies indicate that many such patients receive as much improvement from placebos. Sexual impotence is more often than not psychogenic and relief from any treatment may be the result of psychotherapy. The exhaustion and fatigue of the tired business man is more likely related to a lack of competent assistance in his business than to a lack of hormone. When the number of "forms to fill out" decreases there will be a decrease in the incidence of the "male menopause." A patient with genuine male menopause or a eunuch will be greatly benefited by the administration of the male hormone. Not only will he feel better, but there will be an increase in musculature, deposition of bone

and other objective findings, both laboratory and clinical, such as more normal sex response, lowering of the voice, improvement in genital development, condition of the skin, hair and so forth. To repeat, I question only the incidence of the male menopause.

THE ADRENAL MEDULLA

There is no known syndrome associated with the underfunction of the adrenal medulla.

Paroxysmal hypertension is usually due to an adrenal medullary tumor, a *pheochromocytoma*. This is the rarest of all tumors of the endocrine glands. The usual history is one of sudden, marked rises of the blood pressure with severe vasomotor symptoms due to the paroxysmal outpouring of large amounts of adrenin from the tumor. Roth and Kvale¹⁰ have described the use of histamine to establish the diagnosis. A single injection of a small amount of histamine produces a typical attack. The treatment is, of course, the surgical removal of the tumor, during the operation care must be exercised not to produce another attack. To do this manipulation of the tumor must be avoided until the vessels are clamped.

THE ADRENAL CORTEX

Addison's disease is, of course, the result of destruction of the adrenal cortex from tuberculosis or of simple atrophy. All physicians have seen cases of Addison's disease and recognize the pigmentary changes (not always present), the loss of weight and strength, the lowering of the level of sodium, chlorides and sugar and the elevation of potassium and urea in the blood, and the signs and symptoms of acute adrenal failure. Treatment consists in substitutional therapy, replacing the necessary electrolyte constituents and administering available hormones. Theoretically, the ideal treatment should be the administration of a whole adrenal cortical extract. The chief obstacles in this treatment are, first, the expense and, second, the fact that the extracts are not as potent as seem desirable. The time may come when a more potent, less expensive extract will be available. The extract from the adrenal glands of hogs may prove more active since this extract contains more of the "blood sugar raising" principle than do present commercial products. The only synthetic hormone of the adrenal cortex which has had extensive clinical use is desoxycorticosterone acetate¹² which can be administered hypodermically, by subcutaneous implantation of pellets, by the usual oral method or sublingually. This hormone is the most potent "salt and water retaining" hormone of the cortex but has no "blood sugar raising" effect. It has two disadvantages, first, the expense and, second, its incompleteness. If synthetic hormones are to be used, a mixture of desoxycorticosterone acetate with other fractions which will aid in other functions

(carbohydrate metabolism, for example) is needed. To date corticosterone and Kendall's fraction E are not available for clinical trial.

Certainly too much valuable hormone is being wasted in the treatment of patients whose condition cannot be diagnosed as adrenal cortical failure. I confess to being "allergic" to the term "subclinical" which is used frequently when adrenal cortical failure cannot be diagnosed definitely. There is no doubt but that there are different grades of severity of any disease but it is doubtful whether the use of adrenal

TABLE 1—SYNDROMES ASSOCIATED WITH DISTURBANCES OF ENDOCRINE GLANDS

Gland	Overproduction	Underproduction
Posterior pituitary	None known	Diabetes insipidus
Anterior pituitary	Gigantism, acromegaly, Cushing's syndrome	Dwarfism, infantilism, Fröhlich's syndrome (?), Simmonds' disease (cachexia), Sheehan's syndrome
Thyroid	Adenomatous goiter with hyperthyroidism and exophthalmic goiter	Myxedema, cretinism
Parathyroid	Hyperparathyroidism	Parathyroid insufficiency
Pancreas	Hyperinsulinism	Diabetes mellitus
Adrenal medulla	Paroxysmal hypertension	None known
Adrenal cortex	Hyperadrenal cortical state	Addison's disease
Sex glands	Teratoma and Leydig's cell tumor (male), arrhenoblastoma, granulosa and theca cell tumors (female)	Menopause and other clinical pictures resulting from deficient function of the sex glands, eunuchoidism,

cortical hormone in any form is advisable unless there is evidence of failure of this gland. Tests are available for use in doubtful cases^{5, 9}

COMMENT

In this brief article attention has been given to some of the real and some of the "supposed" disturbances. An excellent summary of other supposed disturbances is given by Reifstein as follows:

"1 Fat boys with genitalia 'lost' in fat usually do not have Fröhlich's syndrome.

"2 Mental defectives have normal endocrine glands

"3 Congenital disorders (Mongolian idiots, Laurence-Moon's syndrome, etc.) are congenital but not endocrine disorders

"4 'Spotty' syndromes (alopecia areata, Paget's

fibrosa disseminata, etc) are 'spotty', but hormones do not affect one arm and not the other'

"5 End-organ unresponsiveness does not mean abnormal glands (American Indians do not raise beards)

"6 Obesity is not 'typed' according to glands, it usually results from polyphagia and abulia and not endocrine dysfunction

"7 Normal endocrine glands characterize most psychopathic (homosexual, etc), psychoneurotic or psychotic persons

"8 Obscure diseases usually are not made lucid by incriminating the endocrines"

SUMMARY

The real disturbances are summarized in table 1

THE DIAGNOSIS OF PRIMARY HYPERPARATHYROIDISM

F RAYMOND KEATING, JR.

THE emergence of hyperparathyroidism as a clinical entity is a comparatively recent event. It was unfortunate, but inevitable, that hyperparathyroidism should first be identified in cases of a disorder of bone known as osteitis fibrosa cystica. This circumstance has given rise to two erroneous concepts regarding this disease: first, that it is a great rarity, and second, that it inevitably occurs in association with osteitis fibrosa cystica. The first misconception springs from the second, and the second is a natural consequence of the history of the disease.

Von Recklinghausen⁴⁰ described osteitis fibrosa cystica in 1891. Askanazy¹³ and later Erdheim⁹ noted the association of this disease as well as other malacic diseases of bone with enlargement of the parathyroid glands. That adenoma of the parathyroid glands could be the cause of osteitis fibrosa cystica was not proved until 1925, when Mandl^{26, 27} successfully treated this condition by excising a parathyroid adenoma. DuBois and his associates,²¹ a year later, showed that the chemical and clinical abnormalities observed in a case of von Recklinghausen's disease were identical with those which followed the administration of an excess of parathyroid hormone to experimental animals. Barr and his colleagues,¹⁶ in 1929, was the first in this country to report the successful removal of a parathyroid adenoma from a patient with osteitis fibrosa cystica. Similar reports appeared thereafter with increasing frequency.

In 1930, Bauer, Albright and Aub¹⁸ reported the first of a series of important observations on the clinical and physiologic aspects of hyperparathyroidism. To a remarkable and unparalleled degree, these investigators have pioneered the subsequent studies of this condition. In 1934 Albright, Aub and Bauer³ called attention to the frequency with which renal calculi occurred in cases of hyperparathyroidism and osteitis fibrosa cystica, and they demonstrated that hyperparathyroidism could occur and be recognized in cases in which there was no evident disease of bone. By 1937 Albright, Sulkowitch and Bloomberg⁶ could report thirty-five cases of proved hyperparathyroidism, in twelve of which there was no evidence whatever of skeletal involvement.

Albright and Bloomberg² in 1934 were the first to show that renal disease was a more common manifestation of hyperparathyroidism than was disease of bone. The surgical management of parathyroid disease was thoroughly developed by Churchill²¹ and Cope.²³ The pathologic changes of the parathyroid glands in cases of hyperparathyroidism were studied by Castleman and Mallory,¹⁹ of Boston, who with Albright, Sulkowitch and Bloomberg⁷ have reported a total of seven cases of primary hypertrophy of the parathyroid glands an-

entity not thus far encountered elsewhere. As judged by published case reports, hyperparathyroidism has remained a rare disease and generally is recognized only in the presence of extensive disease of bone.³² By contrast, by 1942, Cope²⁴ and Albright were able to report a total of sixty-seven cases in which the presence of hyperparathyroidism was proved at operation, a series far larger than that observed by any other group of investigators. I am happy to acknowledge, therefore, that I have drawn freely from the observations and experience of Albright and his associates.

The first case of hyperparathyroidism observed at the Clinic was reported by Wilder⁴⁰ in 1929. For many years, the diagnosis was made very infrequently. Alexander, Kepler, Pemberton and Broders¹⁰ in 1944 were able to collect only fourteen cases of proved hyperparathyroidism that had been observed at the Clinic in a period of fourteen years, namely, from January, 1929 to September, 1942. Considering the much greater incidence of the disease encountered by Albright and his associates at Boston, it appeared reasonable to assume that, at the Clinic as well as elsewhere, the presence of the disease was being overlooked. It seemed possible that the criteria which we had established for the diagnosis of this disease were unduly rigid. Early in 1943, a definite attempt was made to improve diagnostic accuracy by soliciting the co-operation of internists, urologists and surgeons.

In a period of approximately two and a half years, that is, from September, 1942 to January 31, 1945, inclusive, the presence of hyperparathyroidism was proved by operation in twenty-four cases. This is in marked contrast with the fourteen cases in which the presence of the disease was proved in the previous fourteen years. Our findings in the twenty-four cases fully confirm the observations of Albright and his associates. In seven, or 29 per cent, of the twenty-four cases, there was a clinical picture of classic osteitis fibrosa cystica. Minimal lesions of the skeleton were present in nine, or 38 per cent, of the cases but in eight, or 33 per cent, of the cases there was no evidence whatever of osseous lesions.

PRIMARY HYPERPARATHYROIDISM

Hyperparathyroidism is classified as secondary when it results from compensatory hyperplasia of the parathyroid glands due to some other disease such as nephritis or rickets. It is classified as primary when no such etiologic factor is present.

Primary hyperparathyroidism is nearly always caused by one or, occasionally, two adenomas of the parathyroid glands. The tumors which produce hyperparathyroidism are small and more often than not are impalpable. They may occur retrosternally and may be overlooked even when the neck is explored surgically. There are a number of instances in which two or even three operations have been necessary before the tumor could be located.

Hyperfunctioning parathyroid tumors which show unequivocal clinical evidences of malignancy are exceedingly rare.^{20 30} Alexander and his associates¹⁰ described cytologic changes, which in their opinion warranted a diagnosis of adenocarcinoma in twelve of the fourteen parathyroid tumors in their series. Castleman and Mallory,^{10 20} on the other hand, have regarded all of the parathyroid tumors which they have observed as benign adenomas. Irrespective of the pros and cons of the pathologic interpretation of these tumors, it is generally agreed by all investigators that the great majority of such tumors lack the biologic characteristics of malignant lesions. These tumors rarely recur, invade or metastasize, but there have been a very few isolated instances to the contrary.

Cope²⁵ and Albright have observed seven cases in which primary hyperparathyroidism was associated with a curious enlargement of all four parathyroid glands. Histologically, the glands were composed of giant water clear cells. Secondary hyperparathyroidism, on the other hand, is accompanied by hyperplasia of the chief cells.^{20 43}

Symptoms—Primary hyperparathyroidism is protean and most variable in its clinical manifestations. Albright¹ divided the symptoms which may be encountered into three groups: (1) symptoms produced by the chemical changes in the blood, (2) symptoms produced by involvement of the urinary tract and (3) symptoms produced by involvement of the skeleton.

Symptoms Resulting from the Chemical Alterations in the Blood—Hyperparathyroidism is characterized by hypercalcemia and hypophosphatemia. These findings are the reverse of those encountered in parathyroid tetany. One would expect, therefore, to encounter symptoms which represent the converse of tetany and this is, indeed, the case. Pronounced muscular atony occurs and, with it, weakness, fatigue, constipation, anorexia, loss of weight, nausea and vomiting are sometimes encountered. Excepting in instances of severe hypercalcemia, these symptoms may be vague and in cases in which there is minimal alteration of the chemistry of the blood they often are absent. Changes in the electrocardiogram and in the electric excitability of skeletal muscle have been described by DuBois and his associates.³¹

Symptoms Resulting from Involvement of the Urinary Tract—Such symptoms may be due to (1) chemical changes in the urine per se, (2) the formation of renal calculi and (3) the production of parenchymatous renal disease.

Uncomplicated hyperparathyroidism always produces hypercalcinuria and hyperphosphaturia. This excessive loss of minerals is accompanied in some instances by conspicuous polyuria and polydipsia. At times these are so severe as to lead to a mistaken diagnosis of diabetes insipidus. Polyuria is not universally present, however, and its presence or absence cannot be correlated with the degree of calcinuria which is present. Even when a significant degree of polyuria is absent,

in our experience the urine usually is found to have a low specific gravity

Excessive excretion of calcium and phosphorus leads to the formation of renal stones in a high proportion of cases. In twenty, or 80 per cent, of twenty-four cases observed in the past two years, renal calculi were present. As one would expect, some of the stones were composed of calcium phosphate but, for reasons not understood, most of the stones contained calcium oxalate. The stones which occur in hyperparathyroidism may produce all the symptoms and complications common to renal calculi from any source.

In some cases, calcium is deposited in the renal substance, probably in the renal tubules. This results in nephrocalcinosis, a diffuse calcification of the renal parenchyma associated with sclerosis and destruction of renal substance which may progress to a stage where serious renal insufficiency occurs. The condition is generally regarded as irreversible even though the hyperparathyroidism is eliminated. Baker and Howard¹⁴ have reported a case of hyperparathyroidism, nephrocalcinosis and renal insufficiency in which, after excision of a parathyroid tumor, a remarkable degree of recovery at first took place. Severe hypertension developed later and the patient died of a dissecting aneurysm.⁸⁸

A serious degree of renal insufficiency can, of course, result from pyelonephritis or hydronephrosis caused by renal calculi. Pyelonephritis and nephrocalcinosis make damage to the kidney by far the most important consequence of hyperparathyroidism and are ample justification (if such be needed) for seeking means of improving diagnostic methods.⁸

Symptoms Resulting from Involvement of the Skeleton—In many cases in which the absorption of calcium from the diet is approximately equal to that lost through the urine, no evident change occurs in the skeleton. In other cases, there may be any degree of skeletal involvement from minimal demineralization to the most profound depletion and disarrangement of the entire skeleton which are characteristic of advanced osteitis fibrosa cystica. Patients with minimal skeletal changes may have no symptoms whatever or, at the most, may have vague aching and pain.

In cases in which the disease is advanced, various tumors, cysts, pathologic fractures and deformities may occur and be accompanied by intense pain and discomfort. Favorite sites for such lesions are the long bones, ribs, pelvis, and the metacarpal and metatarsal bones. Brown tumors of the jaw, so-called epulis, are often but not invariably indicative of this disease. Loss of height, kyphosis and other deformities of the skeleton may be observed.

Pathologically, the osseous lesions show extensive resorption and decalcification of bone with much fibrous proliferation, but the most conspicuous feature is the intense cellular activity resulting from in-

crease in the numbers of both osteoblasts and osteoclasts. Tumors, when encountered, are generally composed of osteoblasts or osteoclasts and usually are described as giant cell tumors. Cysts filled with clear fluid are common, but many of the cystic lesions observed on roentgenographic examination are actually cellular masses.

Signs and Symptoms Encountered in Cases of Mild Hyperparathyroidism.—A perusal of the foregoing account may prove of little value in making the diagnosis of hyperparathyroidism in the majority of cases. Most of the symptoms which have been noted are often absent. The full range of symptoms is to be encountered only in a case of severe "classic" osteitis fibrosa cystica. Even in such a case there is infinite variation as to the occurrence and severity of symptoms. Our recent experience at the Clinic substantiates Albright's observations that cases of "classic" hyperparathyroidism with osteitis fibrosa cystica are a distant minority compared with the large group of cases in which evidence of involvement of bone is minimal or lacking. In the latter cases, not only are all symptoms referable to the skeleton likely to be absent, but those related to the alterations in the blood are often vague and not diagnostic.

Diagnosis.—As with any malady presenting difficulties in diagnosis, it is most important to consider seriously the possibility of hyperparathyroidism in any case in which the symptoms are at all compatible with it. At the present stage of knowledge of this disease, it appears profitable to consider the possibility of hyperparathyroidism carefully in the following cases: (1) all cases of renal stones, (2) all cases in which there is roentgenographic evidence of generalized demineralization of bone, (3) all cases of cysts or tumors of bone and (4) all cases in which there are symptoms referable to the skeleton. In addition, primary hyperparathyroidism deserves serious consideration in cases of urinary insufficiency, in cases of serious muscular weakness and fatigue, and particularly in all cases of polyuria and polydipsia.

Cases in which there are symptoms that are referable to the skeletal system pose few problems excepting in instances in which serious renal insufficiency is also present. Once the attention of the physician is called to the skeleton, the diagnosis of hyperparathyroidism rests upon the demonstration of a specific generalized and diffuse fibrocystic affection of bone accompanied by characteristic chemical changes in the blood and urine.

At the present time, it is not possible to state with accuracy what proportion of patients with renal calculi will prove on careful study to have hyperparathyroidism. Cope²⁴ stated that between 10 and 15 per cent of patients with renal stones who were investigated personally by himself or Albright eventually were found to have the disease. Since it may be that such patients are unavoidably a somewhat selected group the actual incidence may be less than this figure, but there is no doubt that a significant proportion of patients with renal stones

have hyperparathyroidism. The nature of renal involvement or the duration of symptoms cannot provide a safe guide. Although a number of patients in our series had multiple or bilateral renal stones, and often had had renal colic for many years, one patient (case 34) who had severe hyperparathyroidism due to parathyroid adenoma had had

Fig 154—Range of values of serum calcium in thirty-seven cases of proved hyperparathyroidism. The cases are divided into three groups, as follows: Group 1, hyperparathyroidism with classic osteitis fibrosa cystica; group 2, hyperparathyroidism with demineralization or with minimal involvement of bone; group 3, hyperparathyroidism without disease of bone. Within each group the cases are arranged in order of average calcium values. Individual dots in each vertical line represent different determinations of serum calcium in a particular case; the white circles indicate the mean value of serum calcium in that case.

a single renal colic four months previously. In another case (case 22), the only symptom was a single attack of colic which had occurred twelve days previously.

The essential alterations common to all types of primary hyperparathyroidism are hypercalcemia, hypophosphatemia, hypercalciuria and hyperphosphaturia.

Hypercalcemia—The accepted normal value for total serum calcium is 100 mg per 100 c.c., plus or minus 10 mg. The value for total serum calcium is characteristically increased in cases of hyperparathyroidism, but in many instances it may be scarcely above the range of normal values. Figure 154 shows the values for the serum calcium in thirty-seven cases in which a parathyroid tumor was found at operation at the Clinic. In five, or 14 per cent, of the cases, the average value was less than 11 mg per 100 c.c. In eight, or 22 per cent, of the

Fig 155—Range of values of inorganic serum phosphorus in thirty-seven cases of proved hyperparathyroidism. The cases are divided into groups as in figure 154 and arranged in order of average values for phosphorus.

cases, the value was less than 11 mg per 100 c.c. on at least one occasion.

The value for the total serum calcium and, consequently, its diagnostic significance are dependent on the value for the total protein in the serum. The calcium in the serum consists of two principal fractions (1) ionic calcium and (2) calcium proteinate, which is a combination of calcium and serum protein. The value for the calcium proteinate varies with the concentration of serum protein and is not affected primarily by the parathyroid hormone. The value for the ionic calcium is affected specifically by the parathyroid hormone. In cases in which the concentration of serum protein is low, the value for the ionic calcium actually may be increased although the value for the

total serum calcium is normal. Unfortunately, the values for the separate fractions of serum calcium cannot be determined directly but, if the values for the total serum calcium and the total serum protein are determined, the values for the separate fractions of serum calcium can be obtained by means of a nomogram devised by McLean and Hastings^{34, 35}

Determination of the concentration of the serum protein also is of value in distinguishing hyperparathyroidism from such diseases as multiple myeloma and Boeck's sarcoid, in which the concentration of serum calcium is increased owing to an increased concentration of serum protein

Hypophosphatemia—The accepted normal value for inorganic phosphorus in the serum is 3.5 mg per 100 c c, plus or minus 0.5 mg. The value for inorganic phosphorus is significantly lowered in cases of hyperparathyroidism and this change is more constantly present than is hypercalcemia.⁶ Figure 155 shows the values for the inorganic phosphorus in the serum in the thirty-seven cases of parathyroid tumor. In three, or 8 per cent, of the cases, the average values were within the normal range. In eight, or 22 per cent, of the cases, the value was within the normal range on at least one occasion. In cases in which the diagnosis is questionable, the values for the calcium and inorganic phosphorus in the serum should be determined repeatedly in order to learn the significance of minimal changes which often are encountered.

Hypercalcemia—Sulkowitch has devised a test¹⁵ which furnishes a rough estimate of the amount of calcium excreted in the urine. The test is performed in the following manner: Five cubic centimeters of an oxalate buffer mixture* is added to an equal amount of urine that is acid to litmus paper. If the reaction is not acid, the urine should be acidified with a 50 per cent solution of acetic acid. The test tube is inverted and shaken, and the degree of turbidity produced by the precipitation of calcium oxalate is classified as grade 1 to 4. The urine of healthy persons who are receiving a diet that contains a normal amount of calcium will show a slight cloudiness (grade 1) whereas the urine of patients with hyperparathyroidism will show a greater degree of turbidity (grade 2 to 4). Unfortunately, if the urine of normal persons is concentrated or they have ingested excessive quantities of calcium (that is milk) it often will show a grade 2 or 3 response. It is important to eliminate dairy products and nuts from the diet for a day or two preceding the test.

Many patients with hyperparathyroidism have polyuria. Since the Sulkowitch test measures only the concentration of calcium, the large

* The composition of the oxalate buffer mixture is as follows:

Oxalic acid	2.5 gm
Ammonium oxalate	2.5 gm
Glacial acetic acid	5 c c
Distilled water to make	150 c c

volume of urine resulting from polyuria may lead to a negative result when hypercalcinuria actually is present, therefore, the specific gravity must be taken into account.

The Sulkowitch test is useful, therefore, only as a rough guide. A negative result will often rule out hyperparathyroidism if the test is done on a concentrated specimen of urine. A positive result suggests but does not prove, the existence of pathologic hypercalcinuria. In

Fig. 156.—Roentgenologic appearance of the skull in case of hyperparathyroidism with classic disease of bone. There is diffuse military osteoporosis of the skull with thinning and obliteration of the tables

most instances, therefore, I prefer to rely upon quantitative determination of the excretion of calcium in a specimen of urine collected over a period of twenty-four hours. A normal individual on an average diet may excrete 10 to 100 mg. of calcium daily; a person who drinks milk may excrete as much as 200 mg., while patients with hyperparathyroidism will generally excrete considerably more than 200 mg. of calcium daily. If possible it is preferable to determine the excretion of calcium while the patient is on a diet in which the intake of calcium is accurately measured. Such a diet has been described by Bauer and

Aub¹⁷ The average excretion of calcium by most normal individuals who receive this diet is less than 100 mg a day. An excretion of more than 150 mg a day is considered highly suspicious by Albright, and values exceeding 200 mg a day are regarded as definitely pathologic. Hypercalciuria is not peculiar to hyperparathyroidism, however, as it may occur in other conditions associated with rapid demineralization of bone.

Roentgenologic Appearance of Lesions of Bone—In cases in which the skeletal changes are minimal, the only abnormal roentgenologic finding is a mild diffuse milary osteoporosis of the skull. In cases in

Fig 157—Roentgenologic appearance of the hand in case of hyperparathyroidism with classic bone disease. Generalized demineralization, coarsening of the trabeculae and subcortical absorption may be seen.

which the process is more advanced, there may be evidence of mild generalized demineralization, and subcortical resorption, most conspicuous in the extremities. More marked changes include fibrocystic disease, coarsening and widening of the trabeculae, thinning of cortical bone associated with generalized rarefaction of all bony structures, and the appearance of radiolucent areas in the shafts of long bones, the ribs and even the skull. The presence of large cysts and tumors may make the roentgenographic appearance of the skeleton most bizarre. The most important diagnostic criterion is that when pronounced changes are present in bone the entire skeleton is diffusely and visibly

involved. There is no normal bone, and the demonstration of normal bone in such cases rules out the presence of hyperparathyroidism.

The bony changes in hyperparathyroidism have a predilection for the skull (fig 156), the long bones and particularly the fingers (fig 157) and the ribs. Generalized osteoporosis or atrophy of bone, which also affects the entire skeleton, first affects the spinal column and is generally most pronounced in the vertebrae.⁵ Osteitis deformans

Fig 158—Appearance of the dental roentgenograms in case of hyperparathyroidism with disease of bone. The two upper roentgenograms were made a year before symptoms attributable to hyperparathyroidism first appeared. The appearance of the teeth is essentially normal. The lower pair of roentgenograms were made of the same teeth three years after symptoms of hyperparathyroidism appeared. In addition to demineralization the most obvious change is the disappearance of the thin layer of cortex or lamina dura which invests the root of each tooth. It is to be noted that no change has occurred in the density of the teeth themselves.

(Paget's disease), Albright's syndrome, xanthomatosis osseum and solitary tumors of bone are focal, not diffuse, diseases of bone.

Albright⁶ and his colleagues have emphasized the usefulness of dental roentgenograms in the diagnosis of osteitis fibrosa cystica. The lamina dura, a fine layer of cortex surrounding the root of each tooth, tends to disappear in hyperparathyroidism (fig 158). It also may be absent in osteomalacia but usually persists in senile osteoporosis. Demineralization of the jaws with derangement of the bony structure is

also characteristic and may conceivably be evident as an earlier stage than similar changes elsewhere in the skeleton

Significance of Alkaline Serum Phosphatase—The determination of the concentration of alkaline phosphatase in the serum is of little value in the diagnosis of hyperparathyroidism. Alkaline serum phosphatase is apparently derived from osteoblastic tissue, in any event, an increase in alkaline phosphatase is nearly always indicative of accelerated osteoblastic activity. The concentration of alkaline serum phosphatase is a measure of disease of bone, not of parathyroid disease. In cases of osteitis fibrosa cystica, the value for the serum phosphatase usually is increased. In cases of hyperparathyroidism in which involvement of bone is minimal or absent, the value for the serum phosphatase is normal (2 to 4 Bodansky units)

Diagnostic Criteria in Cases in Which Hyperparathyroidism Is Complicated by Renal Insufficiency—When renal insufficiency occurs as a consequence of primary hyperparathyroidism, it tends to obscure the characteristic chemical alterations of blood and urine. The concentration of inorganic phosphorus in the serum may be normal or increased and the degree of hypercalcemia tends to be less marked than it is in cases in which renal insufficiency is not present. Albright clearly demonstrated this in a case in which data were obtained before and after a serious degree of urinary insufficiency had developed⁸

The excretion of calcium and phosphorus may likewise be reduced to normal proportions. This was illustrated in one case (case 15) in our series

The patient was a woman, forty-five years of age, who had uncinatate fits and very severe osteitis fibrosa cystica. As a result, innumerable pathologic fractures, many of them in bizarre sites, had occurred. Although symptoms of hyperparathyroidism had been present for only three years, she had a severe degree of renal insufficiency. The urea clearance was 12 c c per minute and the concentration of urea in the blood averaged 60 mg per 100 c c. Notwithstanding the extent of the involvement of bone, the average concentration of total calcium in serum was only 11.5 mg per 100 c c and the average concentration of inorganic phosphorus was 3.0 mg per 100 c c of serum. The excretion of calcium in the urine averaged 35 mg per day. Excision of a parathyroid tumor effected a significant shift in the concentration of calcium and of phosphorus in the serum but apparently did not alter the renal disease.

The accurate diagnosis of mild hyperparathyroidism without disease of bone or with mild disease of bone remains exceedingly difficult. In considering the diagnosis in such instances, Albright stated, "If the serum calcium level itself is not sufficiently high to strongly suggest the disease, one can still be led to the right diagnosis if the serum phosphorus is persistently low, or if the calcium excretion is increased in the urine, or if the clinical picture fits the disease and no other disease. In this group, furthermore, it is important to do repeated determinations as the values fluctuate from the normal range into the definitely hyperparathyroid range"⁶

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hyperparathyroidism consists, first in distinguishing it from other conditions producing hypercalcemia and second, in distinguishing it from other diseases affecting the skeleton in a similar manner. Hypercalcemia occurs in hypervitaminosis D, in multiple myeloma, in some cases of metastatic tumors and occasionally in rickets. Lesions of bone which must be distinguished from primary osteitis fibrosa cystica occur in secondary hyperparathyroidism, osteitis deformans (Paget's disease), osteitis fibrosa cystica disseminata (Albright's syndrome), osteomalacia, multiple myeloma, Boeck's sarcoid, generalized osteoporosis and metastatic tumors.

Secondary Hyperparathyroidism—Hyperplasia of the parathyroid glands, with apparent compensatory increase in parathyroid function, is encountered in chronic renal insufficiency, rickets, osteomalacia, multiple myeloma, and in some cases of carcinomatosis.⁴³

Secondary hyperparathyroidism occurring in consequence of renal insufficiency is believed to be the cause of renal rickets in children^{11, 42, 44, 45} and of renal osteitis fibrosa cystica or renal osteodystrophy in adults.^{20, 43, 44} It has been suggested as the cause of the generalized demineralization encountered in multiple myeloma and metastatic tumors of bone.

Secondary hyperparathyroidism is therefore of importance in differential diagnosis because it may produce demineralization of bone or osteitis fibrosa cystica in primary renal disease and it may produce hypercalcemia and diffuse demineralization in other diseases of bone. In both circumstances, it may at times pose an exceedingly difficult diagnostic problem.

It is very difficult to distinguish primary hyperparathyroidism with osteitis fibrosa cystica and secondary urinary insufficiency from primary renal disease with accompanying secondary hyperparathyroidism and renal osteitis fibrosa cystica. The differential diagnosis is more than academic, for, in the case of primary hyperparathyroidism, removal of an offending parathyroid tumor may prolong life, whereas, it is not unlikely that, in primary renal disease with secondary hyperparathyroidism, parathyroidectomy may shorten life.

Renal osteitis fibrosa cystica or renal rickets is usually accompanied by a marked increase of concentration of inorganic phosphorus in the serum, often to 8 or 10 mg. per 100 c.c. The concentration of calcium in the serum may be normal or slightly increased. The concentration of serum alkaline phosphatase is usually increased. The urinary insufficiency is usually of marked severity and long standing. In many instances, the correct diagnosis will be expedited by a clear-cut history of glomerulonephritis or of polycystic kidneys. There is usually a chronic acidosis with reduction of plasma bicarbonate owing to loss of fixed base.⁴ An antecedent history of renal disease, severe acidosis, a high value for inorganic phosphorus in the serum and a normal con-

centration of serum calcium may make the differential diagnosis simple in a given instance but one can imagine circumstances in which it might prove impossible to distinguish the two conditions. In adults, the roentgenologic appearance of the bones may be indistinguishable in the two conditions. In children, in addition to fibrocystic changes, there are broad irregular epiphyseal disks similar to those seen in true rickets⁴⁸

Some idea of the complicated relationships which may occur may be obtained from a most unusual case reported with postmortem findings by Downs and Scott²⁷. The patient, who died of urinary insufficiency, was found to have a parathyroid adenoma, hyperplasia of all non-adenomatous parathyroid tissue, demineralization of the skeleton and nephrocalcinosis. The alterations in the chemistry of the blood were suggestive of secondary hyperparathyroidism. The authors made the reasonable suggestion that the patient initially had primary hyperparathyroidism resulting from the hyperfunctioning parathyroid adenoma. They assumed that this induced nephrocalcinosis, with subsequent renal failure which led to the development of secondary hyperplasia of the nonadenomatous parathyroid tissue and secondary hyperparathyroidism superimposed on the primary disease¹.

Other Diseases of Bone—Serious diagnostic difficulty occasionally may be encountered in cases of multiple myeloma, Boeck's sarcoid and rarely in cases of metastatic carcinoma of bone. In these conditions, the concentration of calcium sometimes may be increased. The concentration of inorganic serum phosphorus in these conditions is generally normal or increased. In multiple myeloma and in Boeck's sarcoid, the hypercalcemia is often, but not always, accounted for by the degree of hyperproteinemia. Biopsy, aspiration of bone marrow and the demonstration of Bence-Jones protein in the urine are often of great assistance.

In generalized osteoporosis, or primary atrophy of bone, demineralization is apparently related to failure of osteoblastic activity rather than to increased absorption of bone. The roentgenoscopic appearance of the skeleton differs markedly from that in osteitis fibrosa cystica. The process is generally most marked in the spinal column and pelvis and less marked in the skull and extremities, the reverse of the distribution generally encountered in hyperparathyroidism. The concentrations of calcium, inorganic phosphorus and alkaline phosphatase in the serum are normal. Apparently similar osteoporosis occurs after the menopause, in association with exophthalmic goiter and with Cushing's syndrome.

Osteitis deformans (Paget's disease) and atypical forms of Albright's syndrome^{9, 30, 33} are focal, not diffuse, diseases of bone. Careful scrutiny of the skeleton usually discloses some areas of normal bone, such a finding effectively rules out the presence of hyperparathyroidism. The concentration of alkaline phosphatase in the serum may be in-

creased (at times it is extremely high in osteitis deformans), but the values for calcium and inorganic phosphorus are usually normal and the roentgenologic appearance of the lesions themselves is often diagnostic.

Hypervitaminosis D—Hypervitaminosis D may simulate almost exactly the changes in the blood and urine in hyperparathyroidism and the symptoms which result from such changes. The advent of extremely potent preparations of this substance in recent years has made this an important diagnostic consideration. A patient giving a history of having taken vitamin D in large amounts should be observed for many weeks in order to allow the effects of the vitamin to dissipate before any significance is attached to hypercalcemia and related findings.

TREATMENT

The treatment of primary hyperparathyroidism is surgical. Roentgen therapy has in general proved unsatisfactory,²⁵ although a few favorable reports of its use have appeared.^{12 13 41}

There is no effective medical treatment. The administration of calcium in large amounts will produce a positive calcium balance and improvement in the skeletal lesions, but at very great risk of irreparable damage to the kidneys.⁶ Calcium is, therefore, definitely contraindicated in cases of hyperparathyroidism. The kidneys may best be spared by a diet low in calcium, which of course may lead to further depletion of the skeleton. Nevertheless, if any delay is necessary between the time of diagnosis and surgical ablation of the lesion, a diet low in calcium and containing liberal amounts of fluid is the treatment of choice.

Patients with severe disease of bone and particularly those with a high concentration of serum phosphatase may show severe and intractable tetany postoperatively for several weeks. We have nevertheless preferred total extirpation of the tumor to subtotal removal, as recommended by Cope.²² Patients with minimal disease of bone or with no involvement of bone seldom have tetany postoperatively.

PROTECTION IN ROENTGENOSCOPY

JOHN F BACON AND EUGENE T LEDDY

GENERALLY speaking, protection in roentgenoscopy concerns the prevention of injury of persons working with or near the radiations coming from the x-ray tube, it includes the use of any and all means by which the intensity of these radiations can be reduced to that of the "tolerance dose" By "tolerance dose" is meant that quantity of radiation which may be received by a person repeatedly or at intervals without bodily injury Actually, the term "tolerance dose" is inaccurate and some other term such as "safe dose" should replace it. The rays against which the roentgenoscopist must protect himself come from both the primary beam of the x-ray and the secondary scattering from objects in the path of the primary beam

The basic ideas of using distance and absorptive shielding for protection against roentgen rays were evolved about the same time that dangers of superficial injury through indiscriminate exposure to the rays became obvious At first, the injuries were thought due to electric effects, ultraviolet rays, platinum particles from the x-ray tube and personal idiosyncrasy, and red silk and thin rubber sheets were suggested as protective measures Roentgen himself probably escaped being hurt because he conducted most of his experiments, which were mainly photographic, with the x-ray tube inside a metal box.

In April, 1898, the Roentgen Society in England began to collect evidence on the harmful effects of the roentgen rays Progress on absorptive shielding was, however, slow and confused for some time and, owing either to carelessness or ignorance, injuries and death continued to result The situation was aggravated during the first World War when many diagnostic sets used by the British Army were relatively primitive and a number of prominent roentgenologists became casualties After this, aroused public opinion started the movement toward the better conditions existing today ⁷

In the consideration of present-day protection the men who use roentgenologic equipment and need safeguards must be divided into two distinct groups (1) the well-trained roentgenologist and (2) the relatively untrained general practitioners, surgeons and others who in the course of their practice "do a little x-ray work" Protection is a vastly different problem for each group This was strongly emphasized by Hatchette, who pointed out the much greater risk to the untrained man during operation of roentgenologic apparatus Unfortunately, most of the information, warnings and recommendations are placed before the skilled men—those who need it least—rather than before those most likely to be hurt.

The injuries which may occur as a result of roentgen rays may be

shielding and (3) operating procedures. Of these, the last is considered most significant.

In a study of 135 physicians who came to the Clinic between 1919 and 1935 for advice about or treatment of roentgen ray injury, Riggs and one of us (E T L)¹⁰ found that ninety-one had contracted their injuries during reduction of fractures with the roentgenoscope. Of this number, seventy-eight admitted the use of no protection and eleven began to use lead rubber gloves only after injury had become apparent. Some of these men thought the dermatitis was of an allergic nature, perhaps caused by some soap or disinfecting solution in the operating room. In some instances, after receiving injuries to one hand from overexposure, these men used the other hand, again without protection, and suffered similar injury to it. Injury was recorded both from prolonged exposure at one examination and from cumulative effects of repeated unsafe doses. Of the 135, only eight had had any roentgenologic training, and all these eight had failed to follow the recommended measures of protection until they had been injured. The best protection untrained men can have during their work in reducing fractures under roentgenoscopic control is the presence of a roentgenologist to guide them. If this is not possible, observation of the following rather simple rules will cut the number of injuries markedly.⁹

1 Know the output of the machine and the time it takes the machine in operation to reach an output of roentgen rays which represent the limit of safety to the skin. Calibration of the tube in r per minute is essential.¹²

2 Use an aluminum filter at least 1 mm thick.

3 Determine the lowest intensity of rays which allows satisfactory visualization. The technic may consist of factors such as 55 KV, 3 Ma, an aluminum filter 2 mm thick, and a distance of 16 inches (40.6 cm) between the tube and the top of the table in the reduction of average fractures of the extremities.¹³

4 Be certain of thorough "dark adaptation" of the eyes. This is a common source of failure on the part of men who "do a little x-ray." Not having become sufficiently or at all well adapted they need a considerably greater intensity of beam to see reasonably well. Patience is the secret of success here.

5 Wear lead rubber gloves and manipulate the fragments with the hands outside the beam as much as possible. This is most important. In spite of their clumsiness, bulkiness and general inconvenience, lead rubber gloves should be worn during all stages of roentgenoscopic reduction of fractures. It is obvious that the backs of the fingers and hands are most severely injured during such procedures. The thumbs are protected from the beam by the limb of the patient. This being the case, it is inevitable that at some time during the manipulation the backs of the hands come into the direct beam with little or no protection if gloves are not used.

6 Use roentgenograms instead of the roentgenoscope This is a better method and is a safer and almost as fast a way to check the reduction of fractures The use of fast film with a compact portable machine can produce excellent roentgenograms with practically no loss of time. This is the method used at the Clinic and at some city hospitals where more emergency fracture work is done It is highly satisfactory and is strongly recommended over the use of the roentgenoscope during reduction.

The British X-ray and Radium Protection Committee² recently recognized the great potential danger of roentgenoscopy in the reduction of fractures and made official recommendations concerning protection and proper use of the roentgenoscope No such official suggestions have been made by any international board of safety or by any of the roentgenologic societies in this country during the past seven years The United States Army, however, has recently issued an order prohibiting the use of the roentgenoscope in reduction of fractures.

Another procedure which claims its share of victims is the removal of foreign bodies under the roentgenoscope, which usually is done by general practitioners and surgeons Unfortunately, the rays from an x ray tube cause no sensation in the hands to warn when enough exposure has been sustained Thus a fragmented foreign body or one that is particularly difficult to remove may require a period of time beyond the safe limit of irradiation to the operator's hands

Roentgenoscopic examinations of the thorax in tuberculosis surveys cause a few injuries, mostly to unskilled users of the apparatus Avoidance of injury here as in other work depends on recognition of the chance of being hurt and reasonable protection against it.

The use of the roentgenoscope after or during removal of a renal stone is advocated in some places Here again, lead gloves and constant attention to other protective devices and procedures are most important.

Unfortunately the only qualification for the practice of roentgenology seems to be the possession of roentgenologic equipment. Those who are trained in the use of radiologic apparatus fully understand its Frankenstein possibilities, but in the hands of untrained or careless men these dangers are overlooked The ratio of roentgenologists to men unskilled in the science who come to the Clinic because of irradiation injuries dramatically attests this fact. Many authors advocate the carrying of dental films by physicians while they are either serving or using irradiation equipment. Comparison of the darkness of the films carried with that of films exposed to known amount of the rays may be sufficiently tangible and shocking to stop continuation of overexposure and thus prevent future injury. Modern x-ray machines are as safe and reliable as ever make them. The advertising of such equipment may

part for the false sense of security possessed by many "men who do a little x-ray work" Much information is spread concerning the shock-proof nature of the machine, its ease of operation and excellence of performance, but never—or at least seldom—in this advertising can one find warnings about the risks that the physician takes in operating the machine One cannot condemn the manufacturers of the apparatus, however, since they are no more bound to teach physicians how to operate the machines than are automobile manufacturers expected to teach purchasers how to drive

It has been proved beyond question that the risks of injury sustained by the roentgenologic specialist are negligible in contrast to the high risk run by the casual user of roentgenologic equipment The faults in technic by which an inexperienced or careless operator may exceed the limits of safety to himself may be summarized as follows⁸ (1) lack of technic of examination, (2) excessive "puttering around", (3) incomplete adaptation of the eyes to darkness, (4) too much current and voltage, (5) insufficient filtration in the roentgenologic apparatus, (6) use of too large fields, (7) placing the bare hand in the field, (8) lack of lead rubber protecting gloves, (9) inattention to the time that the roentgen tube has been in operation and (10) ignorance of the protecting devices advocated by the Safety Committee

Looking at the subject of protection from the point of view of the physician who uses roentgenologic apparatus, two general statements stand out Training, common sense and experience are probably the three most important protective devices with which the operator can fortify himself Carelessness and ignorance are the commonest causes of injury from irradiation Ignorance is inexcusable because the recommendations of the safety committees are so clear and concise that all confusion concerning protection is out of the question Carelessness, however, is a common human fault, but if one keeps in mind the potential danger to himself, to the patient and to the associated personnel, carelessness in protection will cease to be a cause of injury The recommendations of the safety committees should be known by everyone and, being known, should be meticulously observed

THE IMPORTANCE OF DIAGNOSING CHRONIC SUBDURAL HEMATOMA

PHILIP H HEERSEMA AND JOHN G FREEMAN

SUBDURAL hematoma has long been recognized as a concomitant or sequel of injury of the head. Because the treatment of this condition has resulted in complete recovery in a high percentage of cases, the condition automatically has been allocated too readily to the sphere of the surgeon, and even more specifically to the neurosurgeon, whereas in confusing cases in which there is no history of trauma the condition may not even receive surgical attention unless the internist is particularly alert. Contributions to this subject within the past twenty years have been preponderantly those of surgeons, which tends to create the impression that the diagnosis of subdural hematoma is primarily a surgical one. Actually, in very many cases of subdural hematoma the disease may be sufficiently confused with nonsurgical inflammatory and cerebrovascular syndromes to make surgical consultation seem superfluous. Therefore, it seems that it is fitting that more emphasis be placed on making the diagnostician, that is, the internist and the clinical neurologist, more aware of the importance of consideration of this condition in cases in which there is evidence of progressive neurologic or mental defects without a definite history of trauma. Although a history of trauma may be elicited retrospectively or at least suspected, it becomes particularly important to proceed on the strength of certain signs and symptoms without an enlightening history if one is to obtain best results from treatment, for treatment is relatively simple once the diagnosis is considered and made.

There are various classifications of subdural hematoma. A simple classification includes three main groups, namely, acute subdural hemorrhage (rather than hematoma), subacute subdural hematoma and chronic subdural hematoma. In this classification, subdural hygroma, which is a posttraumatic collection of fluid resulting from a rent in the arachnoid, is listed as a subdivision of chronic subdural hematoma. This paper deals chiefly with chronic subdural hematoma because the diagnosis of this condition is very difficult and of course is the primary factor in management.

Munro reported 310 cases of subdural hematoma and classified the respective lesions in two main groups: (1) acute mixed subdural hematomas and (2) chronic subdural hematomas. The second group was divided into two subgroups, namely, fluid hematomas and solid hematomas. Under the heading of fluid hematomas, the author included the lesions which many authors have designated as hygromas. A mixed subdural hematoma contains both blood and cerebro-

spinal fluid and even may contain macerated cortical tissue. The consistency of the lesion depends on the relative proportion of the components. According to Munro this type of subdural hematoma always is due to a craniocerebral injury. In 194 of the 310 cases, the hematoma was of the acute mixed type. In 184 of the 194 cases the presence of a major injury of the brain was verified at operation or necropsy.

To the best of our knowledge, the present paper is the second formal paper on this subject that has appeared in the *Medical Clinics of North America*, the first being that of Lord, however. Holmes and Brock each have reported a case of subdural hematoma in this publication. A number of excellent articles on the subject have appeared in the *Surgical Clinics of North America*.

In 1927, Lord reported an interesting case of spontaneous hematoma in which the correct diagnosis was not made until necropsy was performed. The patient was carefully observed and the fact that the correct diagnosis was not made before death is not surprising when one stops to consider that the knowledge about this condition was comparatively meager when this case was observed. If the correct diagnosis had been made before death, operation undoubtedly would have been performed.

Lord gave a report of this case to forty-seven physicians and requested them to study the report and submit a diagnosis. Of the twenty-five who complied with his request, seven made a diagnosis of lethargic encephalitis, six made a diagnosis of some type of syphilis, five made a diagnosis of tumor of the brain and two made a diagnosis of intracranial hemorrhage. In the remaining five instances the diagnosis was cerebellar abscess, abscess of the brain, cerebrospinal meningitis, cerebral thrombosis and myelitis respectively. If a report of a similar case were sent to a group of practicing physicians today a diagnosis of intracranial hemorrhage probably would be made by considerably more than 8 per cent of the recipients and some of them undoubtedly would mention subdural hematoma. It may be assumed, however, that the correct diagnosis would not be made as frequently as it should be. When patients with a chronic subdural hematoma begin to lapse into a state of coma, the condition comprises much more of an emergency than the condition which prevails in the case of the usual space-occupying lesion of the brain. There are few intracranial conditions in which the variation in the state of consciousness can lull one into the false sense of security occasioned by a temporary remission of symptoms in cases of chronic subdural hematoma.

After the possibility of a chronic subdural hematoma has been considered in a particular case and the findings appear to support this possibility, a history of trauma is an important factor but is not essential for diagnosis. The surgical treatment of subdural hematoma has been reasonably well standardized and the results of such treatment are uniformly good.

It is encouraging to note the number of articles on subdural hematoma that have been published within the past twenty years. The literature on this subject is by no means voluminous nor is much to be gained by padding it in the future with reports of large series of cases except to impress physicians with the relatively frequent incidence of this disease and its importance as a clinical entity. However, reports of unusual cases, which enhance one's diagnostic acumen, are obviously valuable. This is exemplified by the two cases reported by McCall and Love. In one of these cases, the history, symptoms and clinical findings were typical. In the other case, however, there was a high degree of choked disk and the only history of trauma was that the patient had received a "ducking" while he had been swimming.

Although there were earlier reports regarding the relationship of the meninges to hemorrhage, it was Virchow in 1857 who first gave a clear histologic description of the reaction of the dura to hemorrhage and it was he who coined the term "pachymeningitis interna hemorrhagica." He entertained the idea that in certain cases the dura became chronically inflamed. He termed this inflammation "pachymeningitis interna chronica." He mentioned that it occurred among insane patients, but he failed to recognize that insane patients were particularly liable to injury. It was his opinion that an inflammatory process was responsible for the primary formation of a membrane which laid the foundation for oozing hemorrhage by reason of capillary growth into the membrane and a susceptibility of the capillaries to rupture. His opinion prevailed for many years and it was not until 1914 that Trotter advanced the idea that trauma easily could cause a rupture of the veins which bridged the space between the pia mater and the cerebral sinuses since these veins were relatively susceptible to rupture by reason of their sharp angulation and rigid fixation in relation to the longitudinal sinus. It was his opinion that even minor traumatic forces exerted in the proper direction could cause a hemorrhage and that the enclosing membrane subsequently would be derived from the organization of the outer layer of the clot. He was the first to emphasize the increased frequency of trauma among alcoholic and insane patients, in whom it was recognized that there was a higher incidence of subdural hematoma than in the average population. From the diagnostic standpoint, one of the most important contributions made by Trotter was his emphasis of the variation of the state of consciousness, which is of value in distinguishing subdural hematoma from tumor of the brain.

It might be said that the diagnosis of subdural hematoma reached its maturity in America with Putnam and Cushing's classic article which appeared in 1925. In this article, the etiologic importance of trauma was stressed, the pathologic and clinical aspects were considered and the operative treatment was reviewed. In 1932, Gardner advanced a plausible explanation of the latent interval in cases of chronic

subdural hematoma. This explanation was supported by experimental evidence. He expressed the opinion that the increase in size of the hematoma and the consequent compression of the cranial contents were due to an osmotic process. It was reasoned that the degenerative products of the hematoma, which contain a large amount of protein, served to draw from the surrounding cerebrospinal fluid, which contains less protein, to enlarge the encysted hematoma. In general, this complemented Trotter's theory that cerebral compression was due to direct bleeding and cerebral compensation.

In 1932, Fleming and Jones reported a series of eight cases and advocated simple drainage by trephination. This was a great advance in the treatment of fluid or semifluid hematomas since it previously had been considered proper to remove a goodly part of the membrane entrapping the clot. In one case, the hematoma was organized and had to be removed surgically. In the remaining seven cases, the contents of the hematoma were removed by irrigation. In most of these cases there was an immediate return of the intellectual and mental function to normal.

ETIOLOGY AND PATHOGENESIS

As we have stated previously, the relation of trauma to chronic subdural hematoma is well established. However, the mechanism of the actual formation of the clot and the cause of the latent period are not so generally agreed upon. The majority of physicians probably agree with Gardner that the increase in the size of the hematoma is due to osmosis. This, incidentally, may also explain the variation in the state of consciousness on the basis of some fluctuation of the volume of the fluid content of the encapsulated hematoma buffered by the compensatory powers of the brain to adjust itself to an acute change in pressure. It is rather well accepted now that both the spontaneous as well as the traumatic type of chronic hematoma may occur, although there are some champions of the role of trauma who can always introduce the irrefutable argument that a traumatic force so mild as to have been completely unnoticed may have been instrumental in the induction of the hemorrhage. On the other hand, however, those who deprecate the high incidence of trauma in cases of subdural hematoma are not willing to subscribe fully to Virchow's idea that pachymeningitis interna chronica precedes the occurrence of chronic subdural hematoma. To sum up the current belief, we would say that the traumatic factor should be considered as one of first importance, that the delay in symptoms represents a partial liquefaction of the encapsulated clot, after which osmosis increases the size of the clot by reason of a higher protein content of the fluid within the capsule as compared with that of the surrounding fluid. The most likely veins whose rupture could produce this hemorrhage are those which bridge the subdural space and rupture at the point of their attachment to the dura on entering into the superior longitudinal sinus. By reason of their position, their

exposure, and the angle of their attachment to the sinus, they are more susceptible to trauma than other vessels of the brain or meninges. Likewise, this may be a reason why so-called spontaneous subdural hematoma also occurs in these sites since these veins are subjected to some type of blood dyscrasia or surrounding inflammatory reaction as a part of general vascular affection and may be rendered so susceptible that activity considered to be entirely normal might be sufficient to result in spontaneous hemorrhage.

The limiting membrane of a subdural hematoma still is a controversial subject. Certain neurosurgeons have cast doubt on existence of an intradural hematoma by stating that they never have seen one. This presupposes that the limiting membrane is the product of the clot and that fibroblasts grow out from the leukocytes or from the neighboring meninges and produce the limiting membrane. This fits in much more closely with the theory that trauma always is an etiologic factor. The adherents of the theory that the limiting membrane of the clot is actually a part of the dura which is split off and that the hematoma is actually intradural also offer some very sound arguments. Baker, for instance, in adhering to this intradural theory, raised the following question: If the clot is subdural and the membrane is formed from the dura (that is, after the clot has occurred on the dura), why would the various cells go all the way to the inner or arachnoid surface of the clot and form a membrane rather than produce a gradual progressive organization of the entire clot? Yet, aside from the encapsulating membrane, the dura may be perfectly normal and remain so after evacuation of the clot. In our opinion, the incidence of both traumatic and spontaneous hemorrhage can be more satisfactorily explained on an intradural rather than a subdural basis. However, it is not the purpose of this paper to deal with the academic aspects but rather to emphasize the practical clinical features of this interesting clinical entity.

MATERIAL

This paper is based primarily on twenty-five consecutive cases of chronic subdural hematoma that were observed at the Clinic in a period of thirty-five months, that is, between January 1, 1941 and November 30, 1943, inclusive. In all of these cases, the diagnosis was proved by operation or necropsy at the Clinic. In general, this series of cases furnishes a concise picture of our experience with chronic subdural hematoma. This series does not include any case in which the patient was an infant. Subdural hematomas of infants comprise a special field. Their diagnosis and treatment have been summarized very well by Ingraham and Matson. The differential diagnosis of chronic subdural hematoma is the problem of the internist. On the other hand, in cases of acute subdural hematoma (hemorrhage), the surgeon should decide when trephination alone or in combination with ventriculography or encephalography should be performed.

SYMPTOMS AND SIGNS

The symptoms of chronic subdural hematoma may be divided into three groups (1) those that are due to a general increase in pressure, (2) those that are due to fluctuation in the volume of the contents of the hematoma and (3) those that are due to local pressure on adjacent structures. Headache is the most frequent symptom that is due to an increase in intracranial pressure. Headache occurred in 96 per cent of the cases which form the basis of this report (table 1). This figure is about the same as similar figures in other reports, for example, headache occurred in 93.6 per cent of a series of cases reported by Kunkel and Dandy. In some cases in which the patients were in coma when

TABLE 1—SYMPTOMS IN TWENTY-FIVE CASES OF CHRONIC SUBDURAL HEMATOMA

Symptoms	Cases	
	Number	Per cent
Headache	24	96
Nausea and vomiting	9	36
Dizziness	7	28
Confusion and defective memory	5	20
Excitement	4	16
Drowsiness	3	12
Convulsions	2	8
Numbness	1	4
Coma	10*	40

* In these cases, the patients were in coma when they were brought to the Clinic.

they were brought to the Clinic, the relatives stated that headache had been the chief symptom. Nausea and vomiting which often are associated with progressive pressure occurred in less than half of the cases in this series. Although dizziness and disturbances of equilibrium do occur, they are of little diagnostic significance. Syncopal attacks are rather rare. Convulsions occurred in only 8 per cent of the cases in this series and the nature of the convulsions did not aid in the localization of the lesions in any of these cases.

It is believed that there is a certain amount of fluctuation in the volume of the hematoma which causes a variation in the intracranial pressure. As a result, a variable state of consciousness occurs. This may

vary from a lapse of memory to aberrations of behavior or frank coma. This change is of great importance in making a diagnosis of chronic subdural hematoma. It is not unusual for a semicomatose state or mental stupor to develop in a few days or even within a few hours. For a number of days preceding this change in the state of consciousness there will be a defect in memory or orientation. The change also may be preceded by headache, drowsiness, vertigo, nausea and vomiting.

TABLE 2—PRINCIPAL PHYSICAL SIGNS AT TIME OF INITIAL EXAMINATION AT THE CLINIC

Physical Signs	Cases	
	Number	Per cent
Slow pulse rate (below 70)	14	56
Choked disk (less than 2 diopters)	9	36
Hyperreflexia, bilateral	8	32
Hyperreflexia, unilateral	1	4
Hemiparesis and spasticity, bilateral	6	24
Hemiparesis and spasticity, unilateral	3	12
Babinski's reflex, bilateral	6	24
Babinski's reflex, unilateral	3	12
Paresis of oculomotor nerve (ptosis of upper eyelid)	5	20
Paresis of oculomotor nerve (limitation of movement of eyeball)	2	8
Paresis of facial nerve	5	20
Unilateral enlargement of pupil (both pupils were homolateral)	2	8
Stiffness of neck	1	4

Symptoms that are due to the pressure of the hematoma on adjacent structures do not occur consistently. Diplopia, ocular palsy, hemiparesis and jacksonian epilepsy usually do not occur until the condition of the patient becomes critical.

In the majority of the cases in which the patients were conscious when they came to the Clinic, the symptoms and signs were of a mild character. If only a cursory examination had been performed, it is entirely possible that, in some cases, treatment might have been di-

between the trauma and the appearance of symptoms, the etiologic role of the trauma should be seriously discounted

There is little relation between the degree of the trauma and the development of a subdural hematoma. In our experience, it seems that a subdural hematoma is more likely to follow a slight injury of the head than it is to follow a serious injury. In this connection, we might add that we wish chiefly to emphasize the diagnosis of chronic subdural hematoma in cases in which there is no history of trauma.

The chief value of examination of the cerebrospinal fluid in cases of chronic subdural hematoma is to rule out the presence of an inflammatory disease. In one case in this series, repeated cytologic and chemical examination of the cerebrospinal fluid disclosed changes that were suggestive of a chronic inflammatory disease but the pressure of the fluid was higher than it is in chronic inflammatory disease and indicated the need for surgical intervention.

In five (20 per cent) of the cases in this series, roentgenographic examination of the skull disclosed that the pineal gland had been displaced to one side. In four of these five cases, this finding was confirmed at operation. The diagnosis may be confirmed by encephalography or ventriculography but neurosurgeons generally are critical of these procedures. Bucy actually suspected that pneumo-encephalography was instrumental in causing a subdural hematoma in one case. Some authors believe that the removal of some cerebrospinal fluid and its replacement with air may interfere with the dynamics of the cerebrospinal fluid sufficient to add to the gravity of the situation in the case of a spatial lesion of the brain.

In half of the cases in this series, electro-encephalography disclosed unilateral delta waves, which aided in localizing the lesion. Rogers said that in his cases of chronic subdural hematoma the electro-encephalogram tended to be of the low potential type but this has not been our experience. In our series of cases, electro-encephalography disclosed generalized delta waves in the affected region but in some cases this finding was too extensive to be of any localizing value. In 38 per cent of our cases, electro-encephalography disclosed generalized delta waves or bilateral delta waves. The extent of the abnormal graph was not unexpected as a hematoma frequently involves an entire hemisphere of the brain. In the remaining 12 per cent of the cases, the electro-encephalograms were normal, which finding must be considered erroneous.

Differential Diagnosis—*Tumor of the Brain*—In cases of tumor of the frontal lobe, there may be a definite change in personality but this develops gradually and insidiously. In cases of chronic subdural hematoma, irritability, mental confusion and disturbances of the sensorium usually develop abruptly.

In cases of subdural hematoma, the symptoms vary, in cases of tumor of the brain, the severity of the symptoms increases progres-

sively Hemiparesis may occur in both diseases, but in case of subdural hematoma a positive Babinski sign or paresis of the cranial nerves is not likely to occur until evidence of a great increase in intracranial pressure has become manifest. A severe degree of choked disk occurs in cases of tumor of the brain in cases of subdural hematoma the degree of the choked disk rarely is greater than 2 diopters. Headache occurs in both diseases. Although it is an important symptom, it is of little value in localizing the lesion. King reported an interesting case in which the patient insisted that an exploratory craniotomy be performed for so-called posttraumatic headache. The operation disclosed a subdural hygroma.

Encephalitis—In cases of chronic subdural hematoma, the presence of drowsiness may cause the disease to be mistaken for encephalitis. In subdural hematoma, drowsiness is likely to be associated with mental dullness in encephalitis, there is no relation between drowsiness and the mental condition of the patient. A diagnosis of encephalitis is made too often in cases of intracranial lesions of obscure origin. Headache, drowsiness, diplopia, restlessness and insomnia are common symptoms of both of these diseases. This error is made because of insufficient regard to the variability of the drowsiness and mental torpor in cases of subdural hematoma. If the encephalitis has become chronic, the number of cells in the cerebrospinal fluid may be increased only slightly and the pressure of the fluid may be within normal limits. If at any time, the pressure of the spinal fluid increases or if there is other evidence of increased intracranial pressure, for example papilledema, a diagnosis of encephalitis should be discounted and serious consideration given to the possibility that a subdural hematoma may be present. In cases of acute encephalitis the temperature usually is increased and one usually encounters a serious disturbance of sleep, abnormal psychomotor activity and cloudiness of the mental status which is more severe than that observed in cases of chronic subdural hematoma.

Cerebral Thrombosis—The differential diagnosis of cerebral thrombosis and chronic subdural hematoma is not difficult if one considers that the latter disease may be present. The clinical picture of cerebral thrombosis is rather constant and is familiar to most physicians. The only difficulty encountered in the differential diagnosis of cerebral thrombosis and chronic subdural hematoma occurs in cases in which an attempt is made to explain an unusual type of "cerebral vascular accident." In cases in which the symptoms fluctuate but become more severe progressively, and especially in cases in which there is an acute episode during which the symptoms become more severe, a diagnosis of cerebral thrombosis should not be made unless there is concomitant evidence of acute shock, cardiac disease, palsy or hemiplegia. In cases of deepening coma in which Babinski's sign is positive bilaterally, a spinal puncture should be performed and the pressure of the cerebrospinal fluid should be determined. If the pressure is increased but the

cerebrospinal fluid is otherwise essentially normal, a subdural lesion probably is present

Syphilis of the Central Nervous System.—In cases of syphilis of the central nervous system, the diagnosis usually can be made by means of serologic tests.

Other Lesions of the Brain—In cases of meningitis and abscess of the brain, there is a febrile reaction and the diagnosis usually is aided by examining the blood and cerebrospinal fluid, in addition to the infectious features of the history

COMMENT

Death occurred in three of the cases in our series but none of the deaths could be attributed to operation. In two of the three cases, the patients were not referred to a surgeon. In these three cases, the patients were more than sixty years of age, that is, at the age at which confusing vascular syndromes are likely to occur. In sixteen of the twenty-two cases in which the patients survived, the results were very good. In at least a third of these cases, the physical condition of the patient returned to normal within a month. In three cases, the patients were having occasional attacks of convulsions when the last follow-up data were obtained. One patient had mild hemiparesis and spasticity. Another patient had periods of aphasia but his condition subsequently improved. In one case, a severe anxiety state occurred after operation.

Bilateral hematomas were found in three (12 per cent) of the cases. This incidence of bilateral hematomas is slightly lower than that reported by some authors but it is high enough to warrant consideration in every case of suspected subdural hematoma.

In most cases of chronic subdural hematoma, the patients withstand trephination better than they do encephalography. In cases in which the presence of a subdural hematoma is suspected, trephination, followed by ventriculography if necessary, is superior to the preliminary introduction of air in making a diagnosis.

Special consideration of the diagnosis of chronic subdural hematoma should always be given, especially if the patient is aged, in the suspected case of intracranial lesion in which variations of mental alertness are noted, the neurologic signs are likewise variable, the headache is persistent and the entire course is relatively brief. This also holds true in those cases in which a history of trauma has not been elicited.

CIRRHOSIS OF THE LIVER PRESENTING THE CLINICAL FEATURES OF XANTHOMATOUS BILIARY CIRRHOSIS, BUT WITH CONFIRMATION AT AUTOPSY

(Follow-up of Case Reported Previously*)

F W HOFFBAUER, M.D, G T EVANS, MD AND C. J WATSON, MD

In a series of cases of cirrhosis of the liver discussed by the present authors in the March 1945 issue of the *Medical Clinics of North America*, one case (Case III) was included which presented the clinical manifestations indicative of the diagnosis of xanthomatous biliary cirrhosis. In the interim since this report, this patient has come to autopsy, the findings of which were so instructive that it was believed they should be recorded as a supplement to the previous report. Reference to this report will reveal that this patient exhibited the characteristic hypercholesterolemia together with multiple xanthomas of the tendon sheaths, in addition to which there was chronic jaundice and manifest evidence of cirrhosis of the liver. Liver biopsy revealed a picture of an ordinary portal cirrhosis, and there was no evidence in the biopsy of intrahepatic xanthomas. As Thannhauser has emphasized, however, it is known that in xanthomatous biliary cirrhosis the obstructing xanthoma may be found only in the larger bile ducts. This patient died in coma exhibiting evidence of severe uremia, and with an obvious pericarditis. It was difficult to determine how much of the coma was due to hepatic insufficiency and how much to renal insufficiency. The blood urea nitrogen was 102 mg per 100 cc. Shortly before death the serum bilirubin was 14 mg per 100 cc, the serum cholesterol was 375 mg per 100 cc, the cephalin cholesterol flocculation test remained 4+. The marked pruritus persisted until death.

The important findings at autopsy were as follows: (1) diffuse fibrinous pericarditis, (2) extensive diffuse hobnail type of cirrhosis of the liver, which weighed 1600 gm. The common duct was not dilated, but near the lower end of the duct a gallstone was found as noted in Figure 159. This was dark in color, and was found to consist almost entirely of calcium bilirubinate. Ether extraction failed to reveal any appreciable amount of cholesterol. Sections of the liver revealed an extensive diffuse portal cirrhosis of Laennec type (Fig 160).

The anatomic findings in this case reveal that it is impossible to make the diagnosis of xanthomatous biliary cirrhosis with any degree of certainty, since in this case the blood chemical findings and the presence of xanthomas of the tendon sheaths were entirely characteristic and in fact strongly suggestive of the condition, yet at autopsy no evidence was obtained of xanthomas in the biliary tract. Nor was there any intrahepatic xanthomatous change such as described by Chvostek and believed by him to have been productive of cirrhosis. It is believed that the stone found in the common duct was a secondary phenomenon since, after seven years of jaundice, the common duct might have been expected to be dilated had the stone been the causative factor in the production of cirrhosis. The fact that the stone was largely composed of calcium bilirubinate and relatively little if any cholesterol suggests that it was simply due to inspissation of the bile, secondary to the reduced bile output of the cirrhotic liver.

SYMPOSIUM ON SPECIFIC METHODS OF TREATMENT

INDICATIONS AND USES OF BLOOD BLOOD DERIVATIVES AND BLOOD SUBSTITUTES

CHARLES A. JANEWAY M.D * WILLIAM BERENBERG, M.D † AND
GRETCHEN HUTCHINS, M.D ‡

I PHYSIOLOGICAL BACKGROUND FOR THE USE OF BLOOD AND ITS DERIVATIVES

Introduction—The discovery of the blood groups by Landsteiner made the transfusion of human blood from one individual to another a safe procedure, while the development of methods for indirect transfusion by the use of sodium citrate as an anticoagulant, and the ingenious device of the "blood bank" have made it a practicable one. In recent years there have been developed a series of blood derivatives—plasma, serum resuspended red cells, and the products of plasma fractionation—which have replaced whole blood in many instances and have had new and important applications to the treatment of disease. In addition to these blood *derivatives*, a number of blood *substitutes* have been proposed and tested the earliest of these being gum acacia, which was first used in 1917. It is the purpose of this clinic to outline, as succinctly as possible, the best practice at present in this rapidly expanding field of therapy.

The rational use of blood and its derivatives presupposes a basic understanding of its physiology. Blood is a complex mixture of components with many different functions and properties and derived

From the Department of Pediatrics, Harvard Medical School and School of Public Health and from the Children's and Infants' Hospitals, Boston.

* Assistant Professor of Pediatrics, Harvard Medical School Visiting Physician, Children's and Infants' and Peter Bent Brigham Hospitals.

‡ Assistant in Pediatrics, Harvard Medical School Junior Attending Physician, Children's and Infants' Hospitals.

from many parts of the body. Because of its multiple constituents, blood has naturally been used for many therapeutic indications. The present trend is toward the use of the specific component needed by the patient whenever it is available, rather than the administration of whole blood for all purposes, as was common practice until a few years ago. This is both more economical and more efficacious. In correcting deficiencies of particular components, two general types of therapy may be used—replacement or stimulation. *Replacement* consists in the passive transfer of the missing component from an outside source and is frequently a matter of urgent necessity. *Stimulation* consists in providing the stimulus to the manufacture of the missing component by the patient, with gradual but more lasting results if the patient is able to respond.

Functional Components of Blood—Blood is a suspension of cellular elements in a fluid matrix, the plasma.

TABLE 1 —CELLULAR ELEMENTS OF THE BLOOD

Physiologic Data			Therapeutic Data		
Component	Source	Function	Replacement	Stimulation	Disease
Red blood cells	Bone marrow	Oxygen transport	Whole blood Resuspended cells	Liver extract Iron Vitamins B+C Thyroid	Hemorrhage Hemolytic anemia Aplastic, myelophthisic and azotemic anemia Pernicious anemia Hypochromic anemia Deficiency Hypothyroidism
Polymorphonuclear leukocytes	Bone marrow	Phagocytosis, defense against infection	(Whole blood)	(Crude liver extract) Stop offending drug or control infection	Agranulocytosis
Eosinophilic and basophilic leukocytes	Bone marrow	?			
Lymphocytes	Lymph nodes	?			
Monocytes	Tissues	Phagocytosis			
Platelets	Megakaryocytes of bone marrow	Clot retraction	Fresh whole blood (Fresh Plasma)	Stop offending drug or control infection	Thrombocytopenic purpura

Parentheses denote treatment of doubtful value

Cellular Elements—From the clinical standpoint, three groups of cellular elements are important—the red blood cells, which normally constitute approximately 40 per cent of the total blood volume, the white blood cells, and the platelets. A brief summary of our knowledge of these components is given in Table I.

Plasma Proteins—Sixty per cent of the total blood volume of a normal individual consists in plasma, an aqueous solution containing many solutes but principally sodium, chloride and bicarbonate ions, glucose, simple nitrogenous com-

TABLE 2 --PRINCIPAL PLASMA PROTEINS OF THERAPEUTIC IMPORTANCE

Physiologic Data				Therapeutic Data		
Component	Type of Protein	Source	Function	Replacement	Stimulation	Disease
Albumin	Albumin	Liver	Maintenance of blood volume available for nutrition	Human serum albumin (Plasma or serum 1 2 3+)	Ambly acids High protein high ca loric diet	Shock Hypoproteidemia
Prothrombin	Beta globulin	Liver	Precursor of thrombin (clotting enzyme)	Plasma 2 Fresh blood	Vitamin K	Jaundice (obstructive) Liver damage Dicoumarin poisoning
Fibrinogen	Globulin	Liver	Precursor of fibrin (ma- trix of clot)	Plasma 2, 3 Fresh blood		Severe liver damage
Hemophilic globulin	Globulin	?	Acceleration of clotting	Plasma 2 (3)		Hemophilia
Antibodies	Gamma globulin	Reticuloendothelial sys- tem	Humoral immunity	Immune serum globulin Pooled (normal) or con- valent plasma or serum	Active immunization	Infectious diseases, mea- sles, infectious hepati- tis, scarlet fever
Complement	Alpha and beta globu- lins	?	Accelerates immune re- action in vitro (Hemolysis, bacterioly- sis)	Plasma 2 (3) Fresh blood	?	?
Isohemagglutinins	? gamma globulin	?	?	Use in blood grouping for transfusion

pounds, and proteins. It is the concentration of the latter (7 per cent) which chiefly distinguishes plasma from its filtrate, the interstitial fluid.

The plasma proteins are a large and diverse group of molecular species ranging from the relatively symmetrical albumin molecule, with its small size and high net charge giving it its osmotic potency, to the long rod-shaped fibrinogen molecule, specially suited to the formation of the tangled fibrillar structure of the clot. In recent years separation of these proteins into fractions in which specific functions are concentrated has been achieved¹ and these products of plasma fractionation, developed from blood collected by the American Red Cross for the armed forces, will undoubtedly find their way into civilian medicine in due time. The principal plasma proteins of importance to the physician have been recorded in Table 2.

Water and Electrolytes—Neither the blood cells nor the plasma proteins would be of much use without water, which is the principal constituent of the body, comprising approximately 70 per cent of its weight. Body water is distributed between three "compartments"—(1) the cells, (2) the interstitial fluid and (3) the plasma—in accordance with complex osmotic equilibria which depend

TABLE 3 —BODY WATER

	Total Volume	Per Cent of Total Body Weight	Principal Cations	Principal Anions	Protein Conc.
Intracellular fluid	35 liters	50	K ⁺ , Ca ⁺⁺ , Mg ⁺⁺	HPO ₄ ⁻	20-30%
Cell Walls					
Interstitial fluid (includes spinal fluid, aqueous humor)	10.5 liters	15	Na ⁺	Cl ⁻ , HCO ₃ ⁻	0.1-1 % (Lymph may run as high as 3-4%)
Capillary Walls					
Plasma	3.5 liters	5	Na ⁺	Cl ⁻ , HCO ₃ ⁻	7%

Plasma and interstitial fluid = extracellular fluid

upon the respective permeabilities of the different membranes separating the "compartments" (see Table 3).² From the practical standpoint, the volume of extracellular fluid is maintained by the kidney which regulates it by its control of the excretion of water and sodium ions, while the volume of plasma is maintained by the plasma proteins, principally albumin, since the capillary walls are largely impermeable to protein molecules although freely permeable to sodium and other ions and small molecules. In any consideration of replacement therapy, it is essential not to forget the importance of the three cardinal solutions for parenteral use—physiological saline for the replacement of extracellular fluid, glucose for the provision of water and calories, and sodium bicarbonate or lactate for the correction of acidosis. Restoration of kidney function is an essential feature of the treatment of shock, and this involves both the restoration of blood volume to provide an adequate renal circulation and the provision of sufficient fluid for excretion.

Laboratory-Control of Replacement Therapy—The accurate, recognition and proper treatment of disturbances of the various functional

INDICATIONS AND USES OF BLOOD

components of blood and body fluids require constant control. One of the chief difficulties in the use of these methods only measure concentrations of substances in the blood, the total amounts present. Thus they are of limited value in the

TABLE 4—OBSERVATIONS OF VALUE IN THE FOLLOWING CONDITIONS:
HEMORRHAGE, TRAUMATIC SHOCK, BURN, AND THE FOLLOWING
FLUID AND ELECTROLYTE IMBALANCE

Observations	Method	Normal Range
--------------	--------	--------------

of blood volume is devised, we shall continue to labor under this handicap

However, it is possible to obtain much valuable information on changes taking place in patients by the combination of a few relatively simple laboratory measurements and clinical observations, which should be routine procedures in any hospital caring for acutely ill patients, particularly surgical patients (see Table 4 and Fig 161)

Fig 161—Schematic diagram of changes in blood volume and principal blood values after loss of body fluids *A*, Normal, *B*, immediately after hemorrhage (note slight hemodilution), *C*, same after adequate replacement with plasma (note anemia), *D*, after plasma loss from burn (note hemoconcentration with normal plasma proteins), *E*, same after saline (note further fall in plasma volume and hypoproteinemia), *F*, dehydration (note hemoconcentration with high serum proteins)

Perhaps the most useful addition to the methods for following the progress of therapy in patients with shock or burns has been the introduction of simple methods for the determination of specific gravity of biological fluids. The so-called "falling drop" method has been used clinically for a number of years,⁸ but recently a new method, making use of copper sulfate solutions, has been introduced.⁴ By this method the specific gravity of whole blood, which is a relatively accurate measure of the hemoglobin concentration, and the specific gravity of the plasma, which is a good measure of the plasma protein concentration, can be determined with a very small sample of blood by any technician in a few minutes, the only equipment necessary being a few bottles of standardized copper sulfate solution and a centrifuge. These two values give the important data for

the proper control of replacement therapy in case of burns, hemorrhage, or traumatic shock. In cases of shock, values obtained with capillary blood are less accurate than with venous blood, which should be drawn without stasis if possible. All specific gravity methods of plasma protein determination although sufficiently accurate for clinical use in most situations, give very erroneous results in instances of the nephrotic syndrome, where the high lipid content of the plasma lowers the specific gravity.

II THE USE OF WHOLE BLOOD

Indications.—**LOSS OF WHOLE BLOOD**—*Hemorrhage*—In hemorrhage one loses all the constituents of whole blood and only whole blood can adequately replace it. When hemorrhage is attended by shock, plasma may be used to increase blood volume while whole blood is being obtained. Fresh blood has no real advantage over properly handled bank blood in the replacement treatment of hemorrhage.

Burns—Although the administration of plasma is the treatment of choice for combating shock due to burns, the transfusion of whole blood is indicated when plasma is not readily available. Even if hemocoagulation is present in the patient, such a transfusion is reasonable for the donor's blood is relatively dilute by comparison.⁵ Whole blood is indicated when the burned patient has suffered significant hemorrhage. Some of these patients develop hemolytic phenomena,⁶ and after the first few days most of them develop secondary anemia of the deficiency type, so that transfusion of whole blood may be indicated in therapy for any of these conditions.

Infections—Acute and chronic infections may be associated with anemia and will therefore benefit by transfusion. In addition, fresh blood may contain antibacterial and antitoxic factors which aid in combating infection. In general, immunotransfusions have proved to be of little value although on occasions blood from carefully selected donors has appeared beneficial in the therapy of hemolytic streptococcus infections.

TRANSFUSIONS FOR RED CELL DEFICIENCY—*Anemia*.—Transfusion is of great value in the treatment of anemia in that it increases the number of red cells and thus increases the oxygen carrying capacity of the blood.⁷ In many instances of sudden severe anemia due either to hemorrhage, hemolysis or bone marrow inhibition, transfusion is often a life-saving procedure. In some of the more chronic forms of anemia, transfusion should be used symptomatically for relief of symptoms, dangerously low hemoglobin, pre- and postoperative care and general support when necessary, while more specific remedial measures are being carried out.

TRANSFUSION FOR WHITE CELL DEFICIENCY—Transfusion has been used in the treatment of agranulocytosis, but its value is only that of a supportive measure. The life of the granulocytes is so short and the numbers infused are so small that transfusion has not proved to be of any clear-cut value in raising the white count.

TRANSFUSION FOR PLATELET DEFICIENCY—Thrombocytopenic purpura attended by significant hemorrhage, anemia or bleeding in a vital area constitutes an indication for transfusion. Since the platelets are rapidly destroyed when blood is stored, fresh blood should be used in these cases.

TRANSFUSION FOR HEMORRHAGIC DISEASES—The value of various specific components in the therapeutic arrest of hemorrhage in hemophilia and bleeding due to hypoprothrombinemia is discussed later. Fresh whole blood may be used when plasma or specific fractions are not available in attempting to stop bleeding in hemophilia or hypoprothrombinemia.

New Developments in Blood Transfusion—**IMPORTANCE OF THE RH FACTOR**—It has been demonstrated⁸ that about eighty-seven per cent of the general white population, irrespective of their blood groups, possess a factor (an agglutinin) in their red blood cells which has been called Rh. These individuals are referred to as being Rh-positive. The other 13 per cent who do not have this factor in their red blood cells are referred to as being Rh-negative. The Rh-negative individuals can form antibodies (anti-Rh agglutinins)⁹ under two circumstances.

1 *When repeated transfusions of Rh-positive blood are given to Rh-negative individuals*. The first time such a transfusion is given there are no ill effects. However, the Rh-negative individual may become sensitized and begin to develop anti-Rh agglutinins. After repeated transfusions with Rh-positive blood, the titer of these agglutinins may become significant. Not all individuals will develop demonstrable anti-Rh under these conditions but the sensitized Rh-negative patient who does may suffer a hemolytic transfusion reaction on subsequent infusion of Rh-positive cells. Once such a reaction has occurred, all future Rh-positive transfusions are apt to produce increasing symptoms of hemolysis.

2 *When an Rh-negative woman bears repeated Rh-positive children, she may develop anti-Rh agglutinins*. Presumably this takes place because of a break in the placental barrier which allows Rh-positive cells from the fetus to enter the maternal circulation and sensitize her. Clinical manifestations of such isosensitization usually do not appear in the first pregnancy of Rh-negative women unless they were previously sensitized by an Rh-positive blood transfusion. After the anti-Rh agglutinins have been formed by the mother they may be transmitted back to the fetus to produce hemolytic anemia of the newborn (erythroblastosis foetalis) in her subsequent Rh-positive offspring. Actually, this phenomenon is seen in only one out of fifteen matings in which the mother is Rh-negative and the father Rh-positive.

Practical Applications—1 Whenever repeated transfusions are contemplated or a previous transfusion has been given, Rh typing should be done and only Rh-negative blood transfused into Rh-negative recipients.

2 Any time that a transfusion reaction occurs, the Rh factors in the recipient and donor must be investigated before another transfusion is given

3 Rh-negative blood must be used in transfusing a woman who has delivered a baby with erythroblastosis foetalis.

4 Rh-negative blood should be used in transfusing newborn infants suffering from erythroblastosis foetalis Rh-positive blood may be used after the infant is two weeks old

5 Rh typing should be carried out prior to transfusing any female who has not passed beyond the childbearing age. The technic employed has been well described^{10 11}

MEDIA PROVIDING LONGER LIFE ON STORAGE.—Much progress has been made in preserving whole blood so that it can be used for considerable time after storage. Among the many solutions proposed, that of Loutit and Mollison,¹² has proved to be satisfactory

The formula now in general use follows

Sodium citrate U.S.P ($\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2\text{H}_2\text{O}$)	1.33 gm.
Citric acid U.S.P ($\text{C}_6\text{H}_8\text{O}_7 \cdot \text{H}_2\text{O}$)	0.47 gm
Dextrose U.S.P	3.00 gm.
Water (pyrogen free) to make	100.00 cc.
25 cc. of this solution to be used for 100 cc of blood.	

If this mixture is kept continuously refrigerated at 6° C., the blood may be safely used twenty-one days after it has been taken. This acid citrate dextrose (A.C.D.) preservative solution has the following advantages (1) It is simple and easy to prepare. (2) It may be safely autoclaved (3) The blood dilution is negligible (4) It is a superior and satisfactory preservative of red cells for at least twenty-one days (5) It produces negligible in vitro hemolysis even after six weeks.

The only significant disadvantage of this solution is that, since the amount of citrate is relatively small the blood must be mixed very thoroughly when taken to avoid clotting Blood should either be filtered before administration or administered with a filter in the line.

THE USE OF GROUP O ("UNIVERSAL DONOR") BLOOD—Recently it has been shown that group O blood may be used without cross matching for universal donor purposes on a large scale with relatively few reactions.¹³ However, some reactions will still occur The safety of such a procedure is greatly increased by adding A and B substances* to neutralize the anti-A and anti B agglutinins, which occur in high titer in the bloods of certain group O subjects Such neutralized O blood produces no more or even fewer reactions than cross-matched blood of the same group as the recipient.¹⁴

RESUSPENDED RED BLOOD CELLS—With the increased use of plasma more attention has been paid to the therapeutic possibilities of the re-

These substances have been commercially prepared by The Eli Lilly Company

TRANSFUSION FOR PLATELET DEFICIENCY—Thrombocytopenic purpura attended by significant hemorrhage, anemia or bleeding in a vital area constitutes an indication for transfusion. Since the platelets are rapidly destroyed when blood is stored, fresh blood should be used in these cases.

TRANSFUSION FOR HEMORRHAGIC DISEASES—The value of various specific components in the therapeutic arrest of hemorrhage in hemophilia and bleeding due to hypoprothrombinemia is discussed later. Fresh whole blood may be used when plasma or specific fractions are not available in attempting to stop bleeding in hemophilia or hypoprothrombinemia.

New Developments in Blood Transfusion—**IMPORTANCE OF THE RH FACTOR**—It has been demonstrated⁸ that about eighty-seven per cent of the general white population, irrespective of their blood groups, possess a factor (an agglutinin) in their red blood cells which has been called Rh. These individuals are referred to as being Rh-positive. The other 13 per cent who do not have this factor in their red blood cells are referred to as being Rh-negative. The Rh-negative individuals can form antibodies (anti-Rh agglutinins)⁹ under two circumstances.

1 *When repeated transfusions of Rh-positive blood are given to Rh-negative individuals*. The first time such a transfusion is given there are no ill effects. However, the Rh-negative individual may become sensitized and begin to develop anti-Rh agglutinins. After repeated transfusions with Rh-positive blood, the titer of these agglutinins may become significant. Not all individuals will develop demonstrable anti-Rh under these conditions but the sensitized Rh-negative patient who does may suffer a hemolytic transfusion reaction on subsequent infusion of Rh-positive cells. Once such a reaction has occurred, all future Rh-positive transfusions are apt to produce increasing symptoms of hemolysis.

2 *When an Rh-negative woman bears repeated Rh-positive children, she may develop anti-Rh agglutinins*. Presumably this takes place because of a break in the placental barrier which allows Rh-positive cells from the fetus to enter the maternal circulation and sensitize her. Clinical manifestations of such isoimmunization usually do not appear in the first pregnancy of Rh-negative women unless they were previously sensitized by an Rh-positive blood transfusion. After the anti-Rh agglutinins have been formed by the mother they may be transmitted back to the fetus to produce hemolytic anemia of the newborn (erythroblastosis foetalis) in her subsequent Rh-positive offspring. Actually, this phenomenon is seen in only one out of fifteen matings in which the mother is Rh-negative and the father Rh-positive.

Practical Applications—1 Whenever repeated transfusions are contemplated or a previous transfusion has been given, Rh typing should be done and only Rh-negative blood transfused into Rh-negative recipients.

2 Any time that a transfusion reaction occurs, the Rh factors in the recipient and donor must be investigated before another transfusion is given

3 Rh negative blood must be used in transfusing a woman who has delivered a baby with erythroblastosis foetalis

4 Rh negative blood should be used in transfusing newborn infants suffering from erythroblastosis foetalis Rh-positive blood may be used after the infant is two weeks old

5 Rh typing should be carried out prior to transfusing any female who has not passed beyond the childbearing age The technic employed has been well described^{10 11}

MEDIA PROVIDING LONGER LIFE ON STORAGE.—Much progress has been made in preserving whole blood so that it can be used for considerable time after storage. Among the many solutions proposed, that of Loutit and Mollison,¹² has proved to be satisfactory

The formula now in general use follows

Sodium citrate U.S.P. ($\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2\text{H}_2\text{O}$)	1.33 gm.
Citric acid U.S.P. ($\text{C}_6\text{H}_8\text{O}_7 \cdot \text{H}_2\text{O}$)	0.47 gm.
Dextrose U.S.P.	3.00 gm.
Water (pyrogen-free) to make	100.00 cc.
25 cc. of this solution to be used for 100 cc. of blood.	

If this mixture is kept continuously refrigerated at 6° C., the blood may be safely used twenty-one days after it has been taken This acid citrate dextrose (A.C.D.) preservative solution has the following advantages (1) It is simple and easy to prepare. (2) It may be safely autoclaved (3) The blood dilution is negligible. (4) It is a superior and satisfactory preservative of red cells for at least twenty-one days. (5) It produces negligible in vitro hemolysis even after six weeks.

The only significant disadvantage of this solution is that, since the amount of citrate is relatively small, the blood must be mixed very thoroughly when taken to avoid clotting Blood should either be filtered before administration or administered with a filter in the line.

THE USE OF GROUP O ("UNIVERSAL DONOR") BLOOD—Recently it has been shown that group O blood may be used without cross matching for universal donor purposes on a large scale with relatively few reactions¹³ However, some reactions will still occur The safety of such a procedure is greatly increased by adding A and B substances* to neutralize the anti-A and anti-B agglutinins which occur in high titer in the bloods of certain group O subjects Such neutralized O blood produces no more or even fewer reactions than cross-matched blood of the same group as the recipient¹⁴

RESUSPENDED RED BLOOD CELLS—With the increased use of plasma more attention has been paid to the therapeutic possibilities of the re-

* These substances have been commercially prepared by The Eli Lilly Company

maining red cells^{15 16} The use of these cells offers the advantage of the economy of using all the constituents of blood as well as providing a method of administering larger amounts of red blood cells with less of an increase in blood volume than if whole blood were used The chief indications for its use are the anemias It is of special value in anemia with cardiac insufficiency where it is desirable to add red cells without increasing the blood volume and hence increasing the load on the heart It is also indicated when red cells are needed by any individual with a relatively normal blood volume The use of resuspended red blood cells is contraindicated in shock, hemoconcentration, burns and hypoproteinemia, unless plasma or albumin are also administered to provide the needed plasma protein

The method employed at the moment is to centrifuge the whole blood, remove the plasma and resuspend the red cells in pyrogen-free isotonic saline This should be stored at 4° to 10° C and discarded if any freezing occurs Scrupulously sterile technic must be employed and if a purplish or black-red color or unusual odor appears the suspension must not be used When once opened for use, any remaining suspension ought to be discarded The suspension should not be warmed and must be filtered carefully before use, or administered through a suitable filter

It is best to use these cells within twenty-four hours after bleeding as their life duration in saline suspension is short, although they have been used up to five days If the cells are packed and resuspended in a relatively small amount of saline they are more fragile The use of resuspended cells is probably only in its infancy There is need for a more satisfactory diluent than saline so as to prolong the effective life of the cells to three to four weeks Under these circumstances the suspension could be held long enough for the completion of sterility tests, and this would probably diminish the chances of transferring diseases such as malaria and syphilis, the agents of which die on storage in the cold for more than a few days

Blood Grouping Technic—Hemolytic transfusion reactions are almost always due to agglutination of the donor's cells by the recipient's plasma With the increased use of group O blood, there has been a tendency to omit preliminary cross matching before transfusion since the donor cells are inagglutinable in any plasma This practice is justifiable *provided the technic used for grouping the donors is above reproach* In using A or B or AB cells where the donor's cells contain agglutinin, reactions may occur if there has been a mistake in grouping either donor or recipient and thus cross matching should always be done before transfusion As has been pointed out above, Rh-negative blood or cells only must be used in certain situations Table 5 shows the standard international blood group classification, which has properly replaced the Moss and Jansky classifications

Blood grouping serum must be of high potency and high avidity for

satisfactory grouping,* since A_2B and A_2 cells may be so weakly agglutinable that they are missed and classed as B cells and O cells respectively. Good serum may be obtained from a number of sources. As a result of the plasma fractionation program, isoagglutinins have been concentrated for the armed forces from the plasma of grouped bloods, yielding a product of high potency which has proved very satisfactory.^{17 18} These preparations are usually issued in the dry state to preserve potency and are reconstituted just before use. Certain

TABLE 5 —BLOOD GROUPS
(International Classification)

	Agglutination of Subject's Cells by Known Serum		Agglutination of Known Cells by Subject's Serum	
	A Serum (anti B)	B Serum (anti A)	A Cells	B Cells
Group O (Universal donor) (Moss IV) (Jansky I)	0	0	+	+
Group A (Moss II) (Jansky II)	0	+	0	+
Group B (Moss III) (Jansky III)	+	0	+	0
Group AB (Universal recipient) (Moss I) (Jansky IV)	+	+	0	

hospitals bleed professional donors for serum. This practice is not justifiable if the serum is standardized against the weakly agglutinable cells of an A_2B donor to be sure it has adequate potency and if a given lot is retested at intervals. Storage of serum at room temperature or the use of contaminated serum is absolutely contraindicated.

III USE OF PLASMA OR SERUM

Properties of Different Forms of Plasma and Serum — Plasma or serum may be used interchangeably in most circumstances, although the latter lacks the fibrinogen, which may occasionally be needed. The British and Canadians have used pooled serum extensively in this war as it does away with the necessity for centrifugation and may be sterilized by Seitz filtration. Their experience indicates that there is little in fact for the old idea that serum gives rise to more reactions than plasma.¹⁹

* Satisfactory serum may be prepared in various commercial laboratories.

plasma Plasma has the advantage that the red cells can be salvaged, and the separation between plasma and cells can be made promptly by centrifugation Plasma may be salvaged from bank blood, which has been stored too long for use as such, but will have an appreciable content of hemoglobin and potassium and a low content of labile constituents such as prothrombin Either plasma or serum should be pooled in lots derived from at least twelve donors This lowers the isoagglutinin content markedly, and avoids the danger of destruction of the recipient's cells which might occur if a large dose of plasma with a high isoagglutinin titer for his cells were used Pooled plasma can be given in large amounts without preliminary cross matching Its sterility should be checked and serologic tests for syphilis made on the individual bloods before release for clinical use

TABLE 6—FORMS OF PLASMA AND SERUM

Form	Storage	Preparation for Use	Colloid Osmotic Pressure	Nutrition	Prothrombin	Fibrinogen	Hemophilic Globulin	Antibodies
<i>Liquid Plasma Serum</i>	Room temp Sterility must be proved	None	+	+	0 0	0 0	0 0	0(1) 0(1)
<i>Frozen Plasma Serum</i>	-10° C for months	Thaw at 37° C	+	+	+	+	+	+
<i>Dried Plasma Serum</i>	Any natural temp for year Use in 2-3 hrs.	Reconstitute with water	+	+	0 0	+	+	+

(1) Antibodies preserved for a number of months if stored at ice box temperatures.

Plasma or serum can be stored for use in several forms Since these forms differ in their content of various functionally important constituents, the physician should be familiar with the properties of each These are listed in Table 6 In the administration of plasma or serum in any form, as with whole blood or resuspended cells, the *inclusion of a suitable filter in the tubing through which the fluid is administered is imperative* to exclude particulate matter

Liquid plasma has the great advantage of being capable of storage without refrigeration and of being available for immediate administration to patients in shock, where speed is essential^{19, 20} It provides the needed colloid, but other functional constituents are lacking for the most part²¹ The labile components are best preserved in frozen plasma²² It must be thawed before use, which takes time Dried plasma must be reconstituted before use, which requires several minutes and means that the package must contain a bottle of sterile pyrogen-free water as well as the bottle of dried plasma It can be shipped and stored under almost any conditions with a fair degree of preservation

of those labile constituents present when the drying was carried out, except prothrombin.²³

Indications—Loss of PLASMA—This occurs at a rapid rate into the injured area in cases of *burns, severe trauma, and peritoneal irritation*. Evidence for the general leakage of plasma through all the capillaries of the body, which has been postulated as characteristic of advanced surgical shock, is lacking. Probably it does occur through the pulmonary capillaries in cases of blast, poison gas, and thermal injuries of the lungs, and in severe pulmonary infections (influenzal pneumonia) and throughout the body in cases of anaphylactic shock and overwhelming infection.

The loss of plasma can be detected by a rising value for the hematocrit, hemoglobin or whole blood specific gravity without a corresponding rise in plasma proteins such as occurs in dehydration. An attempt should be made to keep this value near normal (see Fig 161) by administration of plasma or 5 per cent albumin in saline.

The treatment of shock due to loss of plasma as in burns or peritonitis requires constant attention to a number of details. Once the shock phase is passed, nutritional problems become all-important.^{24 25} Table 4 lists most of the important clinical and laboratory observations which can be used to guide the course of treatment. Special attention should be given to the following:

1 *The state of the peripheral circulation*. A low blood pressure, rapid pulse rate, and poor quality pulse indicates inadequate replacement, and the rate of fluid replacement should be speeded up.

2 *The urine output*. In shock of any type urine output falls markedly as a result of the poor renal circulation. It is vital to administer sufficient water by mouth or glucose solution by vein to provide water for excretion, sufficient salt to keep the volume of extracellular fluid near normal, and sufficient colloid to keep the blood pressure at a point where adequate glomerular filtration occurs. The urine output and nonprotein nitrogen (or blood urea nitrogen) should be followed closely.

3 *The plasma proteins* (specific gravity measurements satisfactory). Enormous losses of plasma occur in the early phases, while there is a tremendous increase in the rate of protein breakdown which persists for a long period after the injury. Consequently it is extremely difficult to keep the level of serum proteins above the edema level. In the first few days of treatment of a burn case huge amounts of plasma may be necessary to sustain the plasma specific gravity. A working formula for the administration of plasma is 100 cc of plasma for every point the hematocrit reading exceeds the normal of 45 in an average sized adult. For children the dose should be scaled down proportionately.

Thereafter plasma should be given as needed to keep the whole blood specific gravity down near normal, the peripheral circulation satisfactory, and the plasma specific gravity near normal. Large

amounts of fluid with salt or sodium lactate should be given by mouth as tolerated and supplemented by saline and glucose by vein as needed to maintain a good urine output. Excessive intravenous saline or glucose will produce a lowering of the plasma proteins and a return of the shock picture. Food should be given in as large amounts as can be tolerated in an effort to combat the wasting of body proteins. The diet should supply a liberal quantity of protein and calories and a generous supply of all the vitamins.

4 *The red cells* Blood should be given frequently in an effort to sustain the hemoglobin level.

5 *Infection* Infection of the traumatized area almost invariably occurs in burns as in war wounds and hence chemotherapy and local surgical treatment are of great importance.²⁰ Infection probably contributes markedly to the development of anemia and hypoproteinemia.

SURGICAL SHOCK—The major component of surgical shock due to trauma or operation is hemorrhage. Whole blood is the treatment of choice, but plasma or albumin should be used to supply the colloid needed to maintain an adequate circulation while blood is being obtained for transfusion. In these cases, plasma or albumin restores the blood volume but the patient develops an anemia, which should be corrected as soon as possible to promote optimal recovery. Five hundred to 1500 cc of plasma (or 25 to 75 gm of albumin) are quite effective in these cases, but no more than 1500 cc of plasma should be given without blood unless none of the latter is available. It is worth emphasizing that, in severe trauma, it is best to treat the patient promptly and if possible before clinical shock is evident.

MEDICAL SHOCK—Peripheral vascular collapse, as manifested by low blood pressure, weak thready pulse, cold, clammy extremities, pallor, anxiety and restlessness, occurs in a wide variety of conditions. Its intelligent treatment demands recognition of the causative factors. Where cardiac disease—acute myocardial failure after a coronary occlusion or cardiac tamponade developing from acute pericarditis—is the chief factor, therapy must be directed at the heart. Where metabolic disorders are the chief cause—the hypoglycemia of insulin shock or hypoadrenalism, the loss of electrolytes characteristic of diabetic coma or Addison's disease—not only is repair of the chemical deficit required (glucose or sodium chloride) but also replacement with the proper hormone. It is in severe infections such as scarlet fever, meningococcus meningitis, typhus fever and ulcerative colitis that the picture of shock is most often seen. Here multiple factors may be operative: (1) reduction in blood volume from loss of plasma through damaged capillaries or from loss of electrolytes by vomiting, diarrhea or sweating, (2) increase in capacity of the vascular system from loss of vasomotor tone, (3) hypoproteinemia, (4) anemia, (5) hyperpyrexia, and (6) acute adrenal insufficiency as a result of massive hemorrhage into the adrenal glands in the rare instance of Waterhouse-Friderichsen syndrome. Control of the infectious process by intensive

chemotherapy and antitoxic therapy (convalescent serum or antitoxin in scarlet fever and antitoxin in diphtheria) is the most essential phase of treatment. However, supportive therapy may tide a patient over the period before specific measures against the infection become effective in reducing the "toxemia," while in diseases such as Rocky Mountain spotted fever^{27a} or ulcerative colitis, for which there is no specific treatment, it may make the difference between life and death.

Supportive therapy should include oxygen for anoxia, saline (preferably given subcutaneously) for dehydration, glucose, vitamins and amino acids for nutritional purposes, adrenal cortical extract and desoxycorticosterone supplemented with saline and glucose if low blood pressure and collapse appear in a patient with widespread purpura,^{27b} blood for anemia, and plasma for shock and hypoproteinemia. Two hundred to 500 cc of plasma may be life-saving in the first few hours of a severe septic infection before penicillin or sulfonamides have exerted their antibacterial effect. A word of caution should be interjected at this point. In severe pulmonary infections, particularly interstitial pneumonia and particularly in infants and small children, the overenthusiastic use of intravenous fluids of any type is apt to produce pulmonary edema and thus to exaggerate the anoxia already present.

DEFICIENCIES OF SPECIFIC PLASMA PROTEINS—HYPOPROTEINEMIA.—In actual fact, *hypoproteinemia is usually hypoalbuminemia*,²⁸ so that its correction involves restoration of the serum albumin level toward normal. For this purpose albumin should obviously be superior to plasma, but although this product of plasma fractionation has been given considerable clinical trial, so far it has been available only for the armed forces. Since the indications for and uses of plasma and albumin are essentially the same in treating hypoproteinemia, these will be discussed together. Until albumin becomes more available, plasma will have to be used in such cases.

The chief clinical manifestation of hypoalbuminemia is edema, although the serum albumin level may be below optimum before this is grossly manifest. Edema may be due to fluid retained in the tissues because of increased retention of salt, or because of lowered osmotic pressure of the blood, or from the activity of both of these factors. The giving of plasma or albumin alone may not suffice to correct hypoproteinemia and edema in certain cases. One should determine the cause of the lowered serum protein level.

CAUSES OF HYPOPROTEINEMIA 1 **Inadequate Protein Intake**—Since food is the natural source of proteins that can be assimilated for the body's use, conditions such as prolonged anorexia, dietary idiosyncrasies, and starvation may be important factors in lowering the protein supply. In these cases serum albumin is utilized to meet the demands of the body, with a resulting gradual fall in its concentration in the plasma. Starvation per se results in a lowering of the metabolic rate, and a more or less diffuse destruction of body protein so that hypoproteinemia is rarely conspicuous. On the other hand, if a patient

eats a relatively small amount of protein in relation to the total caloric intake, hypoproteinemia develops more rapidly

2 *Excessive Protein Loss*—*Loss of protein from the body* occurs in the urine in the nephrotic syndrome, in the fluids removed by paracentesis of rapidly recurring effusions in the serous cavities and in the oozing of plasma from burns, wounds, or skin lesions such as eczema

Increased destruction of body proteins occurs in infections, burns, and after operations or injuries when the catabolic activities may be so greatly enhanced that it is almost impossible to achieve nitrogen balance with any but enormous amounts of protein. As our methods for the treatment of serious infections and burns improve, the nutritional requirements of convalescence assume increasing importance.²⁰

3 *Defects of Protein Metabolism*—*Poor absorption* may be responsible. In certain gastrointestinal diseases such as pancreatic insufficiency or diarrheal disease the amount of hydrolyzed protein absorbed from the bowel may be diminished because of lack of proper enzymes or too rapid passage through the gut. The administration of hydrolyzed protein (amino acids) by mouth makes it possible to obtain a positive nitrogen balance in many of these cases.³⁰

Impaired synthesis is sometimes present. In hepatic disease the organ which manufactures serum albumin is involved. Thus a low serum albumin level may be one of the signs of hepatic failure and is observed in cases of acute hepatitis and particularly in cirrhosis of the liver.³¹

CORRECTION OF HYPOPROTEINEMIA—In the treatment of hypoproteinemia, the administration of very much larger amounts of protein is necessary than would be expected on the basis of the deficit in total circulating protein. Most of the administered protein is apparently stored in the tissues. In hypoalbuminemic dogs fed a very high protein diet, Elman³² has shown that only one-thirtieth of the protein fed could be accounted for by the increase of circulating albumin. Obviously the correction of hypoproteinemia can be most economically achieved by stimulation therapy—namely, a high protein, high caloric diet, sometimes supplemented by amino acids and glucose administered either parenterally or orally. Unfortunately this takes time and the situation may demand rapid correction. Moreover, in the face of the increased breakdown of body protein occurring in infections and after injuries or in hepatic failure this may be ineffectual. Thus parenteral protein feeding has to be used frequently and plasma must be given by slow drip in doses of from 500 to 1000 cc per day. If used, it should be supplemented in a patient who cannot take oral feeding by as many calories in the form of glucose as possible, and by injection of sufficient doses of vitamin B complex and vitamin C to insure good carbohydrate utilization, in the patient who can eat, a very large intake of protein with carbohydrate will increase the effectiveness of the injected plasma by sparing the body proteins.

The remaining plasma proteins that, by their absence, may give rise to specific deficiencies, can also be replaced by giving plasma in the proper form. As indicated in Table 3, frozen plasma contains most of the active components besides the albumin—this is also true of fresh plasma or blood. The components fall into two main groups: the globulins associated with blood coagulation and those associated with immunity.

Prothrombin Deficiency—The administration of vitamin K orally with bile salts or by injection will usually result in a rapid rise in prothrombin time to normal. In certain instances of severe hepatic damage (hepatitis, salicylate or dicoumarol poisoning), this will not be effective and prothrombin should be supplied by frozen or fresh plasma or fresh blood.

Hemophilia—The primary defect in hemophilia appears to be lack of a globulin which accelerates the clotting of hemophilic blood both *in vitro* and *in vivo*. This globulin is quite labile and therefore fresh blood or fresh or frozen plasma (50 to 100 cc. doses) must be used and repeated doses must be given at critical times so as to keep the clotting time near normal. Because the hemophilic globulin is but a small fraction of the total plasma proteins, undesirable side effects from the large amounts of blood and plasma necessary may occur. It is to be hoped that a plasma fraction will be prepared that may provide the active globulin for injection in a small volume.³³

Fibrinogen Deficiency—This rarely occurs except in overwhelming liver damage as in acute yellow atrophy. The prognosis from the disease itself is so poor that repair of the defect in blood coagulation, although it should be attempted with frozen or dried plasma, probably has little to offer the patient.

Convalescent and Hyperimmune Serum and Plasma—The use of human immune bodies in the treatment and prevention of disease has become common practice in recent years.³⁴ A list of the conditions where there is some evidence for their effectiveness follows:

Disease	Agent	Objective	Dose	Results
Measles	Pooled adult serum	Prevention or Modification	10- 30 cc.	Fair
Scarlet fever	Convalescent serum	Treatment	5- 20 cc.	Excellent
	Pooled adult serum		250-500 cc.	Fair
Mumps	Convalescent serum	Prevention	50-100 cc.	Good
	Convalescent serum	Prevention	10- 20 cc.	Questionable
Pertussis	Hyperimmune serum*	Prevention	10- 20 cc.	Excellent
		Treatment	60- 80 cc.	Good

* Hyperimmune pertussis serum may be obtained from the Philadelphia Convalescent Serum Exchange, 1740 Bainbridge Street, Philadelphia, Pennsylvania. A globulin concentrate containing the antibody fraction of such serum is marketed by The Cutter Laboratories, Berkeley, California, under the name of Hypertussis. Other types of human convalescent sera can usually be obtained from various serum centers.

IV USE OF PRODUCTS OF PLASMA FRACTIONATION

It is suggested from the above discussion that since whole blood and plasma have specific indications for therapy in a wide variety of conditions, the individual components would be even more valuable in isolated form. The products of plasma fractionation³⁵ have been given considerable clinical trial, but so far have been available only to the armed forces, except for immune serum globulin.

Human Serum Albumin—This is distributed in 100 cc bottles containing 25 gm of albumin which is equivalent in osmotic effect to 500 cc of citrated plasma. Albumin solution has contained in the past approximately twice the isotonic concentration of sodium chloride, but interest in its use as a physiological diuretic agent has led to the development of a solution of much lower salt content.³⁶ Besides the great conveniences of a small compact package, ready for use without reconstitution or cross matching, and the safety and ease with which it can be administered, albumin has the great advantage that it can be combined in any desired concentration with any of the solutions used parenterally. Five per cent albumin in saline solution is approximately isotonic with plasma and can be used interchangeably with it in the treatment of burns.

Indications for the use of albumin are as follows:

Shock—Albumin provides effective colloid osmotic pressure for the emergency treatment of traumatic shock. It increases blood volume by drawing water from the tissues into the circulation, and in severely dehydrated patients additional saline should be provided for the relief of dehydration.

Hypoproteinemia—In this condition it is the logical solution for replacement therapy, since it provides the maximum amount of protein with a minimum amount of fluid and no extra salt. Thus, rapid increase in the colloid osmotic pressure with mobilization of water from the edematous tissues can be achieved, by the injection of small amounts of material, a particular advantage in pediatric practice. The low salt content of the solution is of importance in the treatment of edematous patients with renal disease.³⁷

Proteins Concerned in Blood Coagulation and Their Derivatives—The formation of a blood clot is the result of a complicated series of chemical reactions. Since we can now isolate some of the substances involved in this mechanism, however, it is possible to "arrest" the process at various stages and use the intermediate products. Thus, prothrombin can be combined with thromboplastin for the formation of thrombin. If this is done quantitatively with a known amount of thromboplastin and a blood of unknown prothrombin content, the concentration of the latter can be determined by the length of time it takes the clot to form—the "prothrombin time." Thrombin itself has found many uses, particularly in the field of surgery. Combined with fibrinogen, it

forms the fibrin which is the meshwork of the blood clot. The conditions under which these two substances are allowed to combine (relative amounts, thickness of mold, drying conditions, etc.), determine the form the fibrin product will take. We have therefore fibrin foam, fibrin film, and other products which may be developed in much the same way as new "plastics" are developed in industry. *Fibrin foam* has wide clinical application in hemostasis. As a base for *thrombin*, it may be dipped in a solution of the latter, applied to a bleeding point and left in place after it has stopped the bleeding, to be reabsorbed as healing takes place. It is particularly useful in neurosurgery, as is *fibrin film*—a sheet-like preparation of fibrinogen plus thrombin with rubbery tensile strength—which may be used as a dural substitute. These substances cause no local irritative reaction. Thrombin itself, or "clotting globulin," has also been obtained from rabbit plasma and is extremely useful in controlling localized external bleeding in hemophiliacs when applied with pressure, particularly in powder form.* Another ingenious use of fibrinogen and thrombin is to inject solutions of these substances separately into the pelvis of a kidney that contains calculi. As the clot forms, a "cast" of the renal pelvis is made, enmeshing the stones so that they are removed with removal of the whole clot. Finally, a film of fibrinogen and thrombin may be useful in the local treatment of denuded areas and burns, especially when such lesions must be protected while the patient is being transported to a place where more extensive therapy can be carried out.

Immune Serum Globulin (Gamma Globulin)—The gamma globulin fraction of pooled human plasma has been shown to contain the antibodies that reflect the immunity status of the donors. By separation of this gamma globulin fraction these antibodies can be concentrated approximately twenty-five times over the starting material, so that it is possible to give the equivalent of 125 cc. of pooled normal serum by the intramuscular injection of 5 cc. of globulin. This fraction theoretically should be able to confer passive immunity for protection of susceptible persons against diseases to which adults have a lasting immunity of a humoral type. Likewise, the gamma globulin derived from normal convalescent or hyperimmune blood should be valuable in the treatment of those diseases in which the corresponding sera are known to be of value.

Immune serum globulin (human) (gamma globulin antibodies) has been prepared in large amounts from the blood collected from normal adults by the American Red Cross. Because the production of human serum albumin for the armed forces has made available more gamma globulin than is needed by these services, arrangements have been made by the American Red Cross for the distribution of excess globulin for civilian use through local health departments.

Immune serum globulin should be distinguished from *immune globulin*—"Hemostatic globulin," prepared commercially by Lederle Laboratories.

bulin prepared from human placentas since it is more potent, better standardized, and gives rise to very few reactions³⁸

The prophylactic use of gamma globulin has been proved for two diseases—measles and infectious hepatitis (epidemic “catarrhal” jaundice)³⁹ The results of available studies on its use are tabulated below

Disease	Given after Exposure, before Symptoms Appear		Treatment after Symptoms Appear
	Prevention	Modification	
Measles	+ (Dose 0.1 cc per lb in first 6 days)	+ (Dose 0.025 cc per lb in first 6 days)	Some effect if given in large dose before rash appears
Infectious hepatitis	+ (Dose 0.1 cc per lb)	Under investigation	Under investigation
Mumps	0	0	0
Chickenpox	0	0	—

Key +, proved effective
0, proved ineffective
—, no studies made

The globulin is injected intramuscularly and in the usual doses causes very little or no local reaction and only rarely mild general symptoms, principally slight fever. It should not be used intravenously. Its most important civilian use is in the prevention of measles after exposure in sick or debilitated children or in the attenuation of the disease in healthy susceptible contacts. The mild disease carries a much lower risk of complications and probably gives rise to permanent immunity, though this has not been proved. Such passive immunization is effective for about three weeks and must be repeated after that interval if the patient is reexposed. Recognition of the mild disease may not always be easy. Fever, malaise and catarrhal symptoms are usually markedly diminished in intensity and duration. The rash may be sparse and transient. The incubation period may appear to be prolonged since the prodromal stage is largely eliminated.

V REACTIONS FOLLOWING INTRAVENOUS ADMINISTRATION OF BLOOD OR ITS DERIVATIVES

The intravenous administration of whole blood, resuspended red blood cells, plasma, or albumin, while relatively safe, may at times be associated with reactions of different types and varying severity. No preparation of gamma globulin suitable for intravenous use has as yet

been prepared and this material should only be employed intramuscularly. The various types of reactions noted are discussed below.

Reactions Due to Physical Causes ("Speed" Reactions).—For the most part, this type of reaction is produced by an excessively rapid rate of infusion. It is unusual to see this type when albumin is employed. The symptoms produced are primarily those of pulmonary edema and cardiac embarrassment or insufficiency. The best treatment is prophylactic employment of a slow rate of injection. If a reaction of this variety is noted, the infusion must be stopped immediately and symptomatic care given.

Reactions Due to Chemical Agents ("Pyrogen" Reactions).—This type of reaction is produced by chemical or bacterial contamination of the fluids administered. Such contamination is most apt to take place in the final handling, the transfusion equipment or the fluids used to fill the circuit before adding the solution to be infused. Within ten to sixty minutes the recipient develops high fever (often up to 105°) and severe shaking chills, which may last for a few minutes or several hours. Prophylactic treatment should be directed toward preventing such reactions by the use of pyrogen-free solutions and equipment. Once such a reaction takes place it is advisable to keep the patient covered with blankets during the shaking chill and then employ antipyretic measures such as rectal taps of cold water, alcohol sponges and salicylate therapy. Aspirin may be given in repeated doses of 0.3 gm. to infants, 0.6 gm. to children and 1.0 gm. to adults. Sodium salicylate may be administered intravenously in the same doses if more rapid results are desirable or if the drug is refused orally.

Reactions Due to Allergic and Anaphylactic Phenomena.—Reactions of this type are seen primarily with the transfusion of whole blood and plasma and are unusual when resuspended red cells or albumin are used. The reactions are due to the presence in the donor's blood of some antigen to which the recipient is sensitive or of some antibody reacting with an antigen present in the recipient's circulation. It results in sneezing, epiphora, urticaria and asthma in the mild cases. The more severe reactions may be attended by dyspnea, cyanosis and collapse. Such reactions are best prevented by using only fasting donors and excluding those who are highly allergic or have recently received vaccines or foreign serum. If difficulty is anticipated in an allergic recipient, a skin test may be performed using 0.1 cc. intradermally of a 1:20 saline dilution of the donor plasma or serum prior to the transfusion. Once such a reaction occurs, it should be treated by the subcutaneous or intravenous injection of 0.5 cc. of 1:1000 adrenalin.

Disease Transmission.—The possibility exists that many diseases could be transmitted from donor to recipient. Actually this happens only rarely. The most important diseases transmitted by transfusions of blood or its derivatives are syphilis, malaria (particularly quartan) and hepatitis (homologous serum jaundice). The symptoms are of course

those of the disease imparted Treatment should be directed towards screening out diseased donors by a careful history, physical examination and routine serology The problem of the transmission of homologous serum jaundice has received a great deal of attention recently,⁴⁰ but so far no satisfactory method of dealing with this problem has been devised Recipients of icterogenic blood or plasma usually develop jaundice two to six months after receiving the transfusion, and the resulting hepatitis may vary from a severe and even fatal disease to one in which symptoms would not be recognized as of hepatic origin without laboratory studies⁴¹

Hemolytic Reactions (Due to Blood Incompatibility)—These reactions, since they are usually due either to mismatching or Rh incompatibilities, are seen only with the use of whole blood, resuspended red cells, or nonpooled plasma The reaction most often occurs after a relatively small amount of blood is injected but may at times be delayed until after a full transfusion depending on the strength of the agglutinin and its speed of action It is wise to avoid transfusing anesthetized individuals, whenever possible, for fear of masking such a reaction The recipient who is experiencing such a hemolytic transfusion reaction becomes restless and anxious He often complains of pain especially over the kidney regions This pain at times is excruciating Chills and fever, dyspnea, vomiting and collapse may soon follow Hemoglobinuria, oliguria and even anuria are fairly common Later icterus appears with anemia Uremia may be present if renal shutdown is prolonged

Again the best prophylaxis is careful blood grouping and cross matching as discussed previously Specific therapy is directed towards

- 1 Alkalinizing the urine in an effort to free any acid hematin precipitated in the kidney, and establishing a flow of urine in oliguric or anuric individuals The measures commonly employed include intravenous one-sixth molar sodium lactate in doses of 500 to 1000 cc in adults and 10 cc/lb of body weight in infants and children, intravenous sodium bicarbonate either as an isotonic solution (1.5 per cent) or hypertonic solutions of 3 to 6 per cent The oral administration of sodium bicarbonate requires dosages of 15 gm per day in adults with the obvious drawbacks of the slow action of oral doses and the difficulty of vomiting when such high doses are employed

If oliguria is marked or anuria is present, the decision as to the amounts and types of fluids to be administered should be guided by chemical and clinical observations An attempt should be made to provide sufficient fluid to keep water available for excretion but not to flood the patient with water in such quantities as to seriously lower the concentrations of electrolytes in extracellular fluid

- 2 Correcting the resulting anemia by the transfusion of fresh compatible blood

- 3 Maintaining the patient with general supportive therapy

VI BLOOD SUBSTITUTES

Blood substitutes are of two types, those derived from natural sources and those from unnatural ones.

Blood Substitutes from Natural Sources—1 **PLASMA PROTEINS FROM OTHER ANIMAL SPECIES**—Since the plasma proteins of different species resemble one another in their physicochemical properties, although differing markedly on an immunological basis, it is natural that one should turn to them as representing the molecules most likely to function physiologically in the human body. The primary difficulty in the therapeutic use of heterologous plasma proteins is that they are usually antigenic, giving rise to delayed reactions of the serum sickness types, and frequently contain antibodies to human cells which give rise to immediate reactions. Nevertheless considerable work has been done upon this problem.

Bovine Plasma.—Wangensteen and his colleagues have shown that the injection of unmodified bovine plasma is attended with a high incidence of immediate and delayed reactions, although the proteins can apparently be utilized in metabolism.

Bovine Albumin.—In an effort to get rid of the immediate reactions, a number of workers have attempted to purify the albumin fraction of bovine plasma with considerable success. Other albumins have likewise been used. No published evidence is available on the ultimate safety of these solutions in man.

Despecciated Bovine Serum.—In an effort to overcome the immediate reactions, Edwards in England has been using a combination of heat and formalin to treat bovine serum. Such treatment has apparently yielded a product which gives rise to few if any immediate or delayed reactions and in which the osmotic properties of the protein, although damaged, are not completely destroyed.

GELATIN AND ITS DERIVATIVES—*Gelatin* has been proposed. Its colloid osmotic pressure, however, is chiefly due to small molecules which are rapidly lost from the circulation while the large molecules which are long and slender have little osmotic effect but marked effect upon blood viscosity and the sedimentation rate. Furthermore, gelatin is an incomplete protein from the nutritional standpoint. *Isinglass* or *fish gelatin* has likewise been proposed and although possibly slightly superior to animal gelatin in physical properties suffers from the same general defects. *Oxypolygel* represents an attempt by chemical manipulation to overcome the inherent defects of the long thin gelatin molecule. Little data on this substance is available. The chief asset of all the gelatin derivatives is that they are, at least, nonantigenic.

Blood Substitutes from Unnatural Sources.—*Gum acacia* was introduced in the last war. Its great defect for repeated injection is that it drives

* The following paragraphs are merely intended as a brief survey of this field. The results of the search for a satisfactory blood substitute do not justify a complete discussion.

the plasma proteins from the circulation and also is slowly deposited in the liver, thus interfering with protein synthesis and ultimately defeating its own ends

Pectin has also been proposed and would appear to suffer from the defects of acacia but very little is known about its ultimate fate

This list could be expanded considerably. So far no blood substitute which fulfills the criteria for a satisfactory therapeutic agent has been discovered, and as long as there is an adequate supply of human blood, plasma and plasma protein fractions, it will be surprising if any substitute can be found to do the job as well as the molecules developed by the process of evolution.

VII SUMMARY

An attempt has been made to summarize the basic knowledge in a very large field of therapeutics. No physician or surgeon can afford not to understand the fundamental principles underlying the proper use of blood, its various derivatives, and the common intravenous solutions. If this clinic has helped to clarify some of these principles and to indicate some of the therapeutic possibilities arising from the separation of blood into its component parts, it will have achieved its objective.

TREATMENT OF COMMON DERMATOSES

JOHN G. DOWNING, M.D. *

THE treatment of cutaneous disturbances is comparatively simple when the causative factor is identified and eliminated. The pruritus of the diabetic disappears with a proper dietary regimen, the inflammatory reactions of rhus poisoning quickly subside after the removal of oil from the skin and the application of suitable wet dressings, lotions and pastes.

Unfortunately the slightest eruption of the skin seems to call for immediate action, even though there may be no pain or itching. Advice is sought and freely given by the relative, neighbor or friend. The original eruption, a transient erythema or a cancer, is no longer recognizable when the patient reaches the dermatologist, due to overtreatment. A large percentage of a dermatologist's clientele is composed of patients suffering from irritations and hypersensitivities resulting from injudicious use of proprietary medicines, the prescribing of wrong medication as a result of mistaken diagnoses, and the prescribing of sensitizing drugs such as the sulfonamides, mercury, resorcin and the cocaine derivatives for topical application. These drugs are valuable when indicated, but their sensitizing faults should be explained to the patient who should test a small area of his skin before extensive application. Any extension of the eruption should be a warning for change of medication.

Routine history should record the previous treatment in sequence. Thorough examination and suitable laboratory procedure should establish a proper diagnosis. Dermatitis venenata from allergens ranks first, by far, in my office list of diagnoses, and in these cases only topical applications are needed.

Topical therapy is still in the realm of trial and error and, from observation of the formulas of some proprietary remedies, it would seem that we have not advanced far from the magic brews of the ancients. A complete knowledge of all dermatologic remedies is impossible and unnecessary. If restrictions became very extreme, I could still relieve a good percentage of my patients with salt vinegar, boric acid, corn starch, water and petrolatum.

As the result of advertising by radio, press and other methods America has become skin conscious. Some try to enhance the beauty of a normal skin, while others attempt to remove the blemishes. The

* Professor of Dermatology and Syphilology, Tufts College Medical School, Professor of Dermatology, Boston University School of Medicine, Dermatologist in Chief at St. Elizabeth's Hospital, the Boston City Hospital and the Massachusetts Memorial Hospitals.

layman may be excused for heeding this propaganda, but not the physician. He has his medical education which should have taught him to consult recent approved textbooks—the United States Pharmacopoeia, the National Formulary, the publications of the American Medical Association and the American Pharmaceutical Association, and lastly the advice of the Council of Pharmacy and Chemistry in dermatology and syphilology, either directly or through its annual volume of New and Nonofficial Remedies. A sufficient knowledge of drugs advocated by experienced dermatologists is necessary, and their indications and contraindications, as well as the proper methods of application, should be known. Printed instructions are of great value, and the physician should know the necessary amount to be used and prescribe neither too much nor too little. An ounce of an ointment is sufficient for only one application to the average adult body.

Psychic Factors—Before prescribing any medication one must evaluate the psychic reaction of the patient to the rebellious outburst of the skin. There is nothing more disturbing to the average individual than an unexpected or recalcitrant disfigurement or disturbance of the skin. The diagnosis, the prognosis and the possible effects of medication must be explained to the patient. No disease should be pronounced incurable unless an unquestionable diagnosis is made of an entity which has been proved to resist all therapy. I have seen cases of psoriasis that did not recur for fifteen or more years. Cases misdiagnosed by more than one experienced observer as pemphigus have healed and remained well. There is a great psychic factor in the background of many cutaneous diseases. It alone may be the cause of pruritus, urticaria, angioneurotic edema, dermatitis factitia, phobias, hyperhidrosis, pompholyx, and changes or loss of hair. In my experience, psychic traumas have caused exacerbations of neurodermatitis, lichen planus and psoriasis. I have seen all three greatly improved by psychosomatic therapy, after proper dermatologic therapy alone had failed. A certain amount of psychotherapy is of value in all types of dermatologic patients. Even a man with a small benign basal cell epithelioma may develop a phobia unless he is assured that this lesion can be cured. Therefore, the first step in therapy should be reassurance, not a defeatist attitude of "try this and see what happens." A knowledge of drugs and their actions will give confidence to the physician which he in turn will impart to his patient. The following briefly summarizes these remedies.

TOPICAL APPLICATIONS

Baths—Baths have a definite value in cleansing and soothing the skin. Since soap is contraindicated, corn starch or a combination of oatmeal and sodium bicarbonate—the so-called *colloid bath*—should be used. The water should not be hot, rather about 98° F.

Wet Dressings—There is nothing more soothing to an acutely in-

flamed surface than wet dressings of solution of boric acid, 2 per cent, or aluminum acetate, 2 to 8 per cent. These should not be allowed to dry on the skin, and should not be used more than twenty-four to forty-eight hours, for they cause maceration.

Powders—Powders are valuable but neglected remedies. They are cooling and drying, and are an excellent method of applying drugs to the skin. The mineral substances are best—talc, zinc oxide, calcium carbonate, magnesium carbonate and kaolin. Because of caking and hardening—a cause of their unpopularity—they are not to be used on oozing surfaces except when alternated with warm, wet dressings. On the unbroken skin they are very soothing and are used frequently in erythrodermas. A reddened, healing area may be protected by a borated talc. All women know the value of face powder to enhance the beauty of the skin and to remove oiliness. The addition of sulfur may be of value in acne. Powders should be used on moist feet and are good prophylactics against some forms of fungous infections. The following is an example

Salicylic Acid	3.0
Zinc Oxide	6.0
Boric Acid, impalpable	12.0
Talc	q.s. ad 120.0

The present Army issue foot powder has the following composition ¹

Salicylic Acid	2.0
Boric Acid	6.0
Zinc Stearate	3.0
Exsiccated Alum	1.0
Starch	10.0
Talc	78.0

When the skin is exposed to constant wetting, as from urine or sweat in a bedridden patient, a fatty powder such as the following² may be used

Magnesium Stearate	12.0
Liquid Petrolatum	12.0
Talc	q.s. ad 120.0

Sulfur and DDT are used for parasiticides.

Lotions.—Lotions are the next step in therapy. They are suspensions of powders and are of value in the treatment of congested and oozing surfaces. The most popular lotion is Calamine Lotion, N.F. VII. This contains a colloidal clay called bentonite, which acts as a medium for suspending the powders in the liquid by producing a gel. A more elegant preparation is made by the addition of Neocalamine Lotion, N.F. VII, in sufficient amount to match the patient's skin, to avoid the "circus clown's" appearance. The addition of phenol, 1 to 2 per cent, and menthol 0.25 to 0.5 per cent, relieves the pruritus. To achieve a fine dispersion of the menthol, it should be dissolved in a small quan

tity of alcohol before being incorporated into the lotion. The pharmacist realizes this necessity and may be depended upon to carry out the procedure without specific instructions to do so. Goodman³ suggests a formula for suspension of colored zinc oxide (calamine or neocalamine)

Stearic Acid	40
Triethanolamine	10
Distilled water	q s ad 1000
To which add	
(a) Prepared Calamine	80
Zinc Oxide	80
or (b) Prepared Neocalamine	150
or (c) Prepared Neocalamine	80
Zinc Oxide	40

Many useful formulas, such as the following,⁴ may be prepared using bentonite

Bismuth Subcarbonate	250
Bentonite, 6%, in Lime Water	ad 1200
Zinc Oxide	60
Talc	60
Sodium Borate	60
Menthol	09
Alcohol	180
Bentonite, 6%, in Lime Water	ad 1200

Pastes—When the acute inflammation has subsided, the use of an oily preparation or a paste is indicated. C. J. White taught that when the skin began to look like a peeling whitewashed fence, then it was time for oily or greasy vehicles. Their action is more prolonged and they adhere to and soften the scales and crusts. A paste is a rather stiff preparation consisting of powders and the vehicle which may be glycerin, hydrocarbons, paraffin, petrolatum, animal or vegetable fats, lard, cocoa butter, yellow wax, various expressed oils, or mixtures of these. Those containing glycerin are watery pastes. Two examples follow.

Starch	120
Distilled Water	240
Glycerin	q s ad 1200
Zinc Oxide,	
Talc,	
Glycerin,	
Distilled Water	aa 300

Those having a base of petrolatum, such as the official paste of zinc oxide, are the most popular. However, as too much zinc oxide is apt to cause a folliculitis on a hairy surface, I prefer the following⁵

Zinc Oxide	2.0
Starch	13.0
Petrolatum	15.0
Solution of Aluminum Acetate	10.0
Lanolin	20.0
Zinc Oxide Paste	30.0

Salicylic acid, sulfur and sulfonated bitumen may be added to pastes, when indicated

Liniments or Emulsions—Pastes are usually used after the application of a lotion. To avoid the writing of two prescriptions, I prescribe a mixture of the lotion and oil, as a liniment or an emulsion, of which Calamine Liniment, N.F. VII, and the cuticolored Neocalamine Liniment, N.F. VII, are excellent examples. When antipruritics are added to these, they must be greatly reduced in amount to avoid irritation, due to the prolonged action of the oil. Pusey's modification⁶ is an excellent one, but an experienced pharmacist is required for its compounding

Tragacanth	4.00
Phenol	0.75
Zinc Oxide	30.00
Calamine	30.00
Olive Oil	120.00
Distilled Water	q.s. ad 500.00
Oil of Bergamot	1 to 2 cc.

Other drugs such as menthol, resorcin and camphor may be added to the above. In cases of marked pruritus, I frequently use the following

Solution of Coal Tar	15.0
Solution of Lead Subacetate	15.0
Olive Oil	80.0
Starch	30.0
Lime Water	q.s. ad 240.0

Mix the solution of lead subacetate with the olive oil and about 15 cc. of lime water. Add the rest of the lime water in very small portions, stirring thoroughly after each addition. When the emulsion has been completed the solution of coal tar and the starch are added.

Liniments used where there is not much oozing are ideal in erythematous-squamous eruptions such as early psoriasis, lichen planus, pityriasis rosea, the various erythrodermas and the subacute stage of contact dermatitides. A favorite prescription of mine in the pruritic type of psoriasis is the following⁷

Solution of Coal Tar	12.0
Olive Oil,	
Bentonite, 6% in Lime Water	50.0
Lime Water	10.0

In prescribing liniments other than those of the National Formulary I generally write the directions for mixing and advise the use of an

electric mixer I usually prescribe the oil-in-water type of emulsion, because I want the medicament to reach the skin. This must be borne in mind when a water-soluble substance such as penicillin is incorporated in these vehicles.

In asymptomatic erythematous and papular eruptions, and macular, scaly eruptions such as pityriasis rosea, if there is no itching, there is no need of local applications. In pruritic eruptions, such as urticaria, there is no need for lotions containing insoluble substances. Simple watery or alcoholic solutions containing 0.5 to 1 per cent of menthol are more cooling and more antipruritic. *Astringent lotions*, such as the following,⁸ are of value in acne.

Precipitated Sulfur	10.0
Spirit of Camphor	10.0
Alcohol	80.0
Solution of Methyl Cellulose, 2% (1500 cps)	30.0
Rose Water	q.s. ad 240.0

Ointments, Creams and Oils.—It is in the use of the final category of dermatologic preparations that complications arise, namely in the use of ointments. I advise the inexperienced student to use an ointment as his last choice. Having no evaporating properties, being comparatively free of water, they cause congestion and irritation. However, when properly used, they are of extreme value. Their sale is, perhaps, the most profitable business of modern times. They are promoted as milady's creams for beauty, the rejuvenators of the old, the rectifiers of nutritional deficiencies, and the cure for all ailments from pneumonia to psoriasis. I saw one that was recommended for cardiac disturbances. They are the subject of tremendous research, and their value for introducing medication by absorption was recognized by the ancients, but apparently forgotten by many modern physicians. One must be mindful of the purpose for which he prescribes an ointment, must realize the danger of the absorption of the drug incorporated, and watch for untoward reactions locally or systemically. Many ointments are messy, obnoxious preparations, stain everything they contact, are difficult to remove, and cause a great economic loss, for, while the patient is using them, he dislikes to mingle with his fellow-workers and stops work.

A glance through pharmaceutical journals will show the efforts of the pharmacist to remedy these faults, which already have been recognized by the makers of proprietary preparations, with consequent increased popularity of their products. Again, the recent use of endocrines and sulfonamides, and the future use of penicillin have stimulated research for the vehicles by which they may best reach and penetrate the skin, an impossibility with petrolatum and lanolin. Fantus⁹ listed the following ointment vehicles: cerates, ointments, cream ointments (cold creams). The cerates, due to the presence of

wax, have a melting point above the temperature of the skin. Therefore, they do not liquefy, stay in the place where they are wanted, and keep the dressing from sticking to raw surfaces. They are useless for applying medication other than volatile substances. Ointments liquefy at body temperature and, to a certain extent, carry the medication to the skin. Cream ointments have water incorporated in them by means of emulsification and give a cooling sensation due to its evaporation, hence the name "cold cream." Their amazing and profitable acceptance as cosmetics has taught physicians and pharmacists to copy them. A favorite prescription of mine for a mild pruritic eruption contains cold cream.

Menthol	0.3
Phenol	0.9
Boric Acid Ointment	29.0
Rose Water Ointment	ad 60.0

Another excellent but somewhat complicated mixture is of the vanishing cream type.

Stearic Acid	10.0
Triethanolamine	1.0
Glycerin	15.0
Distilled Water	34.0
Alcohol	10.0
Rose Water	30.0
Phenol	1.0
Menthol	0.6
Wool Fat	4.0
White Petrolatum	14.0

Melt the stearic acid, wool fat and white petrolatum on a water bath and heat to 80° C. Mix the triethanolamine, glycerin, rose water and distilled water and heat to 80° C. Add the aqueous phase to the oil phase, stirring constantly and allow to cool to 50° C. Add the phenol and the menthol, previously dissolved in the alcohol, and stir until the product is homogeneous.

Salicylic acid in amounts larger than 2 per cent usually breaks down cold creams, but O'Brien found the following cold cream effective in a modification of Whitfield's Ointment.¹⁰

White Wax	13.0
Cerestin	6.4
Mineral Oil	55.0
Sodium Borate	0.6
Distilled Water	25.0

He suggests that, with this base the official strength of salicylic acid and benzoic acid be reduced one-half and that 2.5 per cent of thymol be added.

Benzoic Acid	6.0
Salicylic Acid	3.0
Thymol	2.5
Mineral Oil	2.5
Cold Cream	q.s. ad 100.0

The inclusion of small amounts of some of the newer emulsifying agents in ointment bases facilitates their removal from the body. This is exemplified in the formula which follows,¹¹ in which the base consists of diglycol stearate, 5 per cent, and petrolatum, 95 per cent.

Crude Coal Tar	2 0
Zinc Oxide	2 0
Starch	15 0
Base	15 0

Many excellent washable bases have been recommended by Duemling.¹² In the use of tar, I have had excellent results with the following

Crude Coal Tar	2 0
Sodium Lauryl Sulfate	0 8
Cetyl Alcohol	15 0
Glycerin	5 0
White Petrolatum	14 0
Distilled Water	35 0

The base whose formula follows is an excellent vehicle for ammoniated mercury, phenol, tannic acid, zinc oxide and ichthammol but is not suitable for boric acid and salicylic acid.

Glyceryl Monostearate	15 0
Cetyl Alcohol	15 0
Glycerin	35 0
Diethylene Glycol	35 0

A base which is compatible with all of the substances mentioned above has been recommended by Beeler.¹³

Cetyl Alcohol	15 0
White Wax	1 0
Propylene Glycol	10 0
Sodium Lauryl Sulfate	2 0
Distilled Water	72 0

Cetyl alcohol has the chemical formula $\text{CH}_3-(\text{CH}_2)_{14}\text{CH}_2\text{OH}$. It is manufactured by E. I. DuPont de Nemours, Inc. of Wilmington, Delaware, who also market sodium lauryl sulfate under the trade name of Duponol C. Cetyl alcohol is greaseless, a good emollient, and renders the skin velvety. Its penetrating power in combination with a wetting agent such as sodium lauryl sulfate causes medicaments to be readily transferred through the skin. The effectiveness of wetting agents is based on their power of reducing surface tension between solid and solvent, thus permitting rapid penetration and dispersion of the solid. Because of this property they are useful as detergents and penetrants, and some of these agents are also efficient emulsifiers. Propylene glycol ($\text{CH}_3\text{CHOH}-\text{CH}_2\text{OH}$) imparts ease of spread and softness, and retards the evaporation of water. The above ointment base has been shown to be of the oil-in-water type. Its pH is reported to be within the range of 7 to 9, and is, therefore, well on the alkaline

side. No apparent incompatibilities have been found for this base as far as the experimental work has progressed.

Pectin emulsion and ointments have been tried, but further research is necessary due to incompatibilities. A 15 per cent suspension of bentonite in water has been used as an ointment base on the body and scalp.¹⁴

Kulchar¹⁵ recommends elkonite as a colloidal clay ointment base. Its advantage is that it is fairly adherent, but may be readily removed by gentle washing with water. It is used in a 15 per cent concentration as a gel.

Triethanolamine is an excellent emulsifying agent. I have used it in a cleansing cream for acne for many years.¹⁶

Benzyl benzoate has been found to be effective against pediculosis capitis, and has been used for seven years in the treatment of scabies. A concentrate is made with 2 gm. of triethanolamine, 8 gm. of oleic acid, and sufficient benzyl benzoate to make 100 cc.¹⁷

With the marked increase of industrial dermatitis, many efforts have been made to produce *protective creams* for the worker. The perfect protective cream has not been found, the failure being mainly due to the skin itself. Skins vary, some have an excess of oil, others have an excess of water; some are greasy, others are dry. The soap or the cream must, therefore, be selected for the individual, not for a group of workers. The choice depends usually on the amount of water or oil on the skin. The protective cream should be inexpensive, easily applied and removed, an elegant preparation, not too greasy or drying, and should contain no irritating or sensitizing ingredients. The following¹⁸ is an example:

Stearic Acid	10.0
White Wax	2.0
White Petrolatum	4.5
Triethanolamine	1.5
Glycerin	8.0
Distilled Water	54.0
Talc	20.0
Perfume	as desired

Tar is one of the most useful drugs in dermatology, but patients object to its uncleanness and its staining properties. Many efforts have been made to offset these objections. Tars differ greatly in their composition. An effort should be made to improve the inadequate specifications of the official product. Steam distillates of tar make pleasant preparations, but are not always effectual.

Snake venom has been used in an ointment for chilblains.

Concentrated sulfur pastes have been found by Abramowitz¹⁹ to be of value in pustular psoriasis, infectious eczematoid disease, and scabies. Incorporated with white or yellow petrolatum in a concentration of 30 per cent in cold, 40 per cent in water.

spread on thinly However, in acne rosacea, my favorite is the following

Salicylic Acid	20
Precipitated Sulfur	20
Petrolatum	qs ad 300

This formula is also of great value in impetigo contagiosa

Recently, extensive studies have been made in the use of the cutaneous route,²¹⁻²⁴ rather than injection, of drugs such as endocrines In prescribing ointments, we must always remember the effect desired for the drug incorporated, and watch for undesired effects

INJECTIONS

In 1931 I reported the effect of calcium in pruritic skin affections, with special reference to calcium gluconate, a new compound in this country²⁵ Before this paper was published, a patient with pernicious vomiting, who had miscarried twice as a result of the affliction, was given calcium gluconate intravenously for a severe attack of urticaria, with successful elimination of the urticaria and the vomiting Thus a dermatologist may have been a pioneer in this field However, when I see patients today who have had injections of calcium gluconate day after day, week after week, with no results except the depletion of their pocketbooks, I wish I had never published that report. It is of value in a few acute conditions, but after a few injections calcium can be given by mouth with the same satisfactory result.

The same holds true for other forms of calcium Calcium chloride is very irritating and painful, if any of the solution extravasates into the tissue Calcibronat intravenously and orally gives temporary relief to tense sufferers of neurodermatitis, but it should not be used too long because of the danger of bromism Sodium iodide intravenously had a vogue in herpes zoster, I saw one good result in a case of herpes zoster ophthalmicus but in other cases this treatment appeared valueless

Several cases of carbuncles and furunculosis appeared to be benefited by the use of aolan, but it became unpopular in my practice after abscesses appeared at the sites of injection in two patients Collosal manganese seems to be of value in an occasional case of sycosis vulgaris, but useless in other diseases Sodium thiosulfate gives transient relief from itching in cases of dermatitis exfoliativa from drugs, but I do not believe it shortens the duration of the disease Although it has been claimed that the subcutaneous injection of sodium thiosulfate in situ is a means of preventing inflammation and pain after the accidental extravasation of the salvarsan, I prefer the injection of novocaine into these areas

Enesol, a proprietary compound containing both arsenic and mercury, is of value in the acute cases of lichen planus However, since it has not been available, I have used bismuth subsalicylate with almost

as good results Autogenous vaccine and toxoid should be tried in a stubborn case of acne or recurrent staphylococcal infection of the skin Gold sodium thiosulfate has been recommended for several cutaneous diseases, including psoriasis, but in my experience its chief value is in lupus erythematosus, in the chronic or late subacute stage. It is a dangerous drug I have seen two deaths and several cases of dermatitis exfoliativa following its use.

Parenteral administration of toxicodendrum as a prophylactic method in poison ivy dermatitis may have some value, but I am still unconvinced of its curative effect when used therapeutically I have used it since its introduction, and if the dermatitis showed signs of subsiding after the first injection, I gave another the following day, but no more. If the eruption was worse I did not give a second injection, for I have seen too many cases where I thought the eruption became generalized after these injections I thoroughly agree with the final statement of Stevens in his recent report on the status of poison ivy extracts "The treatment of the acute rash with ivy extracts should be discouraged, because many patients are made worse and there is no satisfactory evidence that any are helped" ²⁰

The value of the parenteral use of vitamins and endocrines is still in the experimental stage, but they do produce remarkable improvement when indicated. When one feels he must give an injection—either for the psychic effect or for want of something to do—the safest procedure is the injection of whole blood, autohemotherapy It is sometimes of value in extensive dermatitis venenata, urticaria and psoriasis. In these days of busy wartime practices and manpower shortage, it is remarkable how few injections are needed when proper internal medication, topical remedies and physiotherapy are used However one should be cognizant of the indications and contraindications, the dosage, and the method of administration. These may be learned from the reports of the National Research Council, such as the recent excellent report on penicillin by Dr Chester Keefer

HYPNOTICS

The choice of hypnotics in cutaneous disturbances is extremely important. In pruritic eruptions they will produce a short period of sleep, but the patient awakes with a terrific outburst of itching This fact is especially true when the barbiturates are used The depressing action of the hypnotic tends to increase the psychosis from which the patient is suffering Owing to their rapid action, paraldehyde and chloral hydrate are the drugs of choice. Chloral should be given in doses of 5 to 10 grains (0.3 to 0.6 gm.) Morphine lowers the threshold of the scratch reflex and should never be used Combinations of aspirin and codeine, although not good hypnotics, give a sense of relief and may be very useful In pruritic eruptions subsequent to phenobarbital therapy, it is well to remember to avoid phenol in local applications.

THE SULFONAMIDES

The dermatologist, enthusiastic at first, early recognized the high incidence of sensitization from topical application of the sulfonamides, but despite his admonitions the general practitioner continued this use until he had a serious reaction in his own clientele. Although these calamities have become so numerous that now the lay public is cognizant and fearful, some pharmacists freely peddle sulfathiazole ointment over their counters and the two largest producers of band-aids continue to incorporate this dangerous drug in this universal first-aid application despite the fact that they are aware of the unfortunate results and of the resolution adopted by the Section of Dermatology and Syphilology of the American Medical Association.

The various sulfonamides are effective in the treatment of infections of the skin due to aerobic organisms such as streptococci and staphylococci. Sulfathiazole is more effective than sulfadiazine, sulfanilamide or sulfapyridine and is the drug of choice. The literature in 1941 advocated its use especially in impetigo. Later, sensitizations began to appear and it was recommended that it be used not over four days. The ointments containing as little as 5 per cent of sulfathiazole were found to cause the largest number of untoward results. Aqueous solutions, lotions and powders cause fewer accidents. However, approved textbooks do not recommend their use, because there are many harmless, time-honored remedies which are satisfactory for the relief of this minor disease.

I am thoroughly opposed to the topical application of these drugs, except in illnesses where withholding them might endanger life or lead to permanent disability, because I have seen too many cases of dermatitis exfoliativa of several months' duration in which the patient suffered untold torture unnecessarily. My worst cases have followed its use in varicose eczema.

All physicians are aware of the dangers of the oral use of the sulfonamide drugs, and as a result any untoward reaction is suspected by the patient owing to previous instruction by his physician, and subsequent confirmation leads to cessation of the drug. Most patients taking these drugs are hospitalized and under close observation, and the all too-frequent cutaneous reactions are readily recognized. With trepidation, I still use these drugs by the oral route in extensive pyogenic infections. I have used them in severe acne in large doses without success. Sulfapyridine, however, has a definite value in some cases of dermatitis herpetiformis. Physicians must remember the photosensitizing properties of the sulfonamides and not expose their patients to sunlight, ultraviolet or x-ray radiation while under treatment with them.

I have come to the conclusion that the dangers of the use of the sulfonamides in the practice of dermatology outweigh their benefits.

ANTIBIOTICS

The phenomenon of antibiosis has been known to mycologists for nearly a century, but its practical application has been realized only recently. The first antibiotic to be successfully developed was *gramicidin*, a substance discovered in the cultures of *Bacillus brevis*. Its restriction to local use stimulated a search for a less toxic substance for internal medication, with the resulting development of penicillin. The substances derived from cultures of the *Bacillus brevis*, namely tyrothricin and gramicidin, are of value in discharging sinuses and pyogenic ulcerations. The substances derived from the higher fungi seem to be less toxic and more selective in their action. Although new agents already are appearing, streptothricin and streptomycin from the actinomycetes group, and patulin from the aspergillus group, penicillin is the one now best known.

PENICILLIN

It has been my good fortune to be able to observe the results of the use of penicillin in the United States, especially in syphilitic infections, ever since the inauguration of the original work by the panel authorized by the Council of Pharmacy and Chemistry at the Evans Memorial Hospital, Boston. The results of the various cooperative groups are now well known through the many publications issued up to the present time.

In the beginning, only cases of syphilis showing a positive darkfield were submitted to penicillin therapy. The rapidity of the disappearance of spirochetes of the *Treponema pallidum* from the lesions in seven to twenty-four hours and their subsequent rapid healing was extraordinary. Herxheimer reactions were fairly common in the early stages but not serious, however, this fact must be kept in mind in treating cardiovascular, ophthalmic and aural disturbances. These reactions did not prevent the further administration of the penicillin.

The doses at first varied until a course of sixty injections, of 20,000 units each, given intramuscularly at three-hour intervals for seven and a half days was accepted as the minimum dosage schedule in primary and secondary syphilis. Later, however, military authorities insisted on larger doses of 40,000 units for the same period; until 2,400,000 units were injected.

There were a few reactions of hypersensitivity, the most common being urticaria. This developed in almost 5 per cent of the patients with occasional joint pains. A vesicular eruption has been reported,²⁷ and I saw a bullous eruption appear in a patient treated for osteomyelitis.²⁸ There was surprisingly little pain at the site of injection, except in cases where the drug was accidentally injected subcutaneously. However, when employing the intravenous route, pain and thrombosis frequently occurred at the site of injection.

Later at the Boston City Hospital and other clinics I observed its

use in congenital syphilis, and late cutaneous and osseous syphilis, with excellent clinical results. Although in my opinion late cutaneous lesions do not respond as rapidly as they did to the old arsphenamine and potassium iodide, still response is fairly prompt. It must be remembered that the use of penicillin is still in the stage of investigation, and positive assertions regarding cures cannot be made until at least a five- or ten-year period has elapsed. Perhaps later the administration of penicillin with an arsphenamine or heavy metal may be the method of choice. However, any drug properly administered at the right time that will give 80 per cent apparent cures must be considered remarkable.

As penicillin became more available, it was used in various cutaneous disturbances, especially those of staphylococcal or streptococcal infection, with varying success. Three cases of severe disseminated lupus erythematosus, two of pemphigus and one of erythema induratum failed to respond to penicillin. One case of hydradenitis responded promptly to 600,000 units, but recurred in a short time. Several cases of extensive cystic acne vulgaris involving the face and entire back had marked temporary improvement, but with the cessation of the injections new lesions immediately appeared, necessitating the regimens previously used in the treatment of the disease. The same was true of syccosis vulgaris. In these cases as high as 2,000,000 units were used with improvement, the eruption recurred after cessation of treatment.

Various types of local applications were used and finally a water-in-oil emulsion was prepared that was found satisfactory. While this preparation has not cured the disease it has markedly reduced the number of lesions, to the satisfaction of the patient. It has been found of value in impetigo contagiosa, provided that the usual cleansing methods are employed, namely washing the face with soap and water and removing the crusts.

One case of pemphigus neonatorum was successfully cured. Two days after birth the patient showed a bullous eruption which rapidly involved nearly all the cutaneous surface. Various sulfa drugs were used internally and externally with no improvement—the eruption continued to spread. On the eighth day I saw the patient and prescribed penicillin. Nineteen injections were given in two and a half days—eight doses of 5000 units and eleven doses of 2500 units—as well as local application of compresses of saline containing 500 units of penicillin per cubic centimeter. The response was almost immediate—within twenty-four hours the patient's temperature dropped, no new lesions appeared, and the old ones rapidly desquamated. In three days the skin was entirely healed except for two extremely adherent crusts, one on the left cheek and one on the right side of the neck. It was interesting to note that a small extremely adherent crust on the side of the neck was frequently daubed with a compress containing saline and penicillin. On the sixth day a reaction of irritation or hypersen-

sitization was noted around this lesion and spreading down onto the neck where the penicillin solution had dripped. This promptly healed without medication after the penicillin was stopped.

One case of chronic furunculosis was relieved as to the lesions present at the time of the injections, but new lesions appeared a few days after the last injection. Several cases of fungous infection of the skin were treated with penicillin ointment and emulsion, with satisfactory healing and disappearance of the pyogenic infection, but the intra-epithelial vesicles of dermatophytosis persisted after the cessation of treatment and required the use of fungicides. Two severe cases of impetiginous eczema of the lower legs, one in a twelve-year-old boy, were treated with 500,000 units every three hours with prompt improvement. However, when the pyogenic infection was cleared, there still remained the eczema to be treated with suitable therapy.

I believe penicillin will be a disappointment in general dermatologic therapy, not because the drug has not proved its worth, but because too much will be expected of it. Even when contraindicated, it will be tried with great expense and disappointment to the patient.

VITAMINS

Although man since his origin has had to maintain life by adequate intake of food, it is strange that accurate knowledge of nutrition is so meager. The study of vitamins has stimulated research in the field of nutrition to the advantage of dermatology. There is much to be known about these heretofore unknown substances so essential to normal growth and metabolism, and existing in minute quantities in our daily diet.

Deficiency of vitamins manifests itself frequently in cutaneous disturbances. At first it was thought that a given syndrome might be traceable to inadequate intake or storage of a single vitamin, but now it is recognized that it is due to multiple vitamin deficiency, though perhaps the loss of one may initiate the onset. Dietary fads, poverty, pestilence and war are frequently attended by stigmas of avitaminosis. The diet may be adequate, but failure to absorb the vitamin properly may result from chronic diarrhea, steatorrhea, pernicious anemia, disturbances of the endocrines and fevers due to infections.²⁰ Jeghers²⁰ in an excellent review describes numerous cutaneous changes of nutritional origin. He states that, in spite of the widespread use of vitamin preparations during the past ten years, the scarcity of untoward effects of excess vitamin ingestion indicates that these occur infrequently—and in general this is true. There are, however, two significant exceptions. Hypervitaminosis D is one of these. This is a condition characterized by hypercalcemia with resultant deposition of calcium in various tissues, which at times leads to a fatal termination. Such were the dangers of the use of massive doses of vitamin D in psoriasis a treatment which is now discarded by experienced dermatologists. He

also cited carotinemia, which may result either from ingestion of only moderate excess of carotene, or from impaired ability of the body to metabolize the amount of carotene present in a normal diet. I have seen cases of generalized pruritus which were relieved when the patient stopped taking large doses of vitamin B.

Vitamin A should be tried in follicular hyperkeratosis, keratosis pilaris, pityriasis rubra pilaris, keratosis follicularis, and loss of skin tissue as from burns and ulcers. It should be given in daily doses of 200,000 units.

Vitamin B complex has been used in many cutaneous diseases with varying success. Favorable results in acrodynia by the injection of 6 mg daily for six days were attributed to thiamine. Occasionally it seems to lessen the pain of postzoster neuritis,³¹ though this relief may be somewhat psychic. Riboflavin has established its place in the treatment of the syndrome of cheilitis, perlèche, the brilliant-red, smooth tongue, and the scaling and keratotic plugging of the seborrheic area of the face, when given in doses of 20 mg daily. If given with accompanying doses of dilute hydrochloric acid, it is useful in the cutaneous eruptions and keratitis of acne rosacea. Recently I have been giving large doses in the treatment of the discoid type of lupus erythematosus with some success. Nicotinic acid has been a lifesaver in pellagra. It seems to be of value in the acute pyogenic infection. Pyridoxine has been recently reported as being of value in acne.³² Liver extract parenterally or orally combined with iron certainly helps the adolescent chlorotic miss with acne.

Crandon and his associates³³ proved the need of *vitamin C* in certain types of hyperkeratotic lesions, petechial hemorrhages, and failure of wound healing. Sulzberger found that large amounts of vitamin C will raise the sensitivity threshold and that there will consequently be less danger of reaction to the use of the arsphenamines in syphilis. Cornbleet³⁴ showed its value in the removal of melanin deposition of Addison's disease.

Despite the many reports of the value of *vitamin D* in psoriasis, acne vulgaris, pemphigus and scleroderma, in my hands it has been a failure. It stimulates healing in x-ray burns.

Vitamin P is recommended in purpuras and for regulating vascular permeability, but not sufficient work has been done to prove this contention.

Vitamins to be of value must be used in adequate dosage and though they apparently are harmless, we still have a great deal to learn about them. They are expensive. The lay public is thoroughly victimized and vitaminized by advertising propaganda, and it is the physician's place to stem this tide, unless a definite deficiency in the patient is recognized.

ENDOCRINES

Recent advances in endocrinology when applied to dermatology have initiated new concepts of therapy. The influence of the endocrine glands on the skin and its appendages is well known. Endocrine dysfunction has been frequently recognized by the cutaneous stigmata—loss of hair accompanied by a dry, scaly, infiltrated skin suggests hypothyroidism, the yellow, bronze or amber color of the skin must lead to the discovery of a dysfunction of the adrenal glands, the polychromatic patch on the lower leg may prompt the diagnosis of diabetes. These monoglandular aberrations may respond dramatically to hormonal therapy. However, the endocrine system is complex. No gland functions independently, they are closely interrelated, and a dysfunction of one overthrows the normal hormonal equilibrium so that response from one endocrine preparation is often disappointing.

The cutaneous changes at the menopause, namely the keratotic palms and soles, generalized pruritus and kraurosis, may respond dramatically to estrogens, but often they do not. Similarly in the male, the dry, scaly keratotic, pruritic skin may occasionally respond to androgens.

Acne vulgaris appears at puberty and therefore suggests a possible endocrine dysfunction. However, few youths escape the blemishes of this happy age, and it appears strange that nature should institute pathologic endocrine function at this period of life. Affecting so many it is a fertile and profitable field for endocrine experimentation, and in my opinion dangerous for uncontrolled unscientific therapy. The field of endocrine therapy in cutaneous diseases has tremendous possibilities, the response to fortunate selection of a hormone, and the giving of dosage previously determined by experimentation is often dramatic, as in the remarkable recovery after the use of 300 mg. of testosterone propionate, when sulfa drugs, penicillin and vitamins had failed in a young girl prostrated by a disseminated lupus erythematosus showing the complete picture described by Libman and Sachs. Only in carefully studied cases of acne vulgaris, however, as in all cutaneous diseases, should hormones be used, for they are potent substances, and their indiscriminate use may lead to disastrous results.

PHYSICAL THERAPY

Light, x-ray and radium play an important role in dermatologic therapy. Unsightly pigmentation may follow their use in acute eruptions, and all physicians are cognizant of the severe injury to healthy tissue which results from their misuse.

The air-cooled lamp is useful in acne, erysipelas, mycotic and pyogenic infections, pityriasis rosea and various forms of alopecia. The water-cooled mercury lamp is used in pitted scars resulting from acne, furuncles, carbuncles, ulcers, localized patches of psoriasis, tuberculosis of the skin and nevus flammeus.

The combination of crude coal tar and ultraviolet ray in the treatment of psoriasis has been used in Boston for many years with great temporary success. The tar is rubbed into the skin before ultraviolet radiation. Goeckerman,⁸⁵ however, perfected this treatment and first reported its success with patients at the Mayo Clinic.

CONCLUSION

This article may seem to be one of destructive rather than constructive criticism. However, it is the result of many observations made in private practice. It is an attempt to add emphasis to the fact that many cutaneous diseases are self-limited, and are best treated conservatively with well-established beneficial methods of therapy. It is not an attempt to condemn experimental research for new advances, but to advise the physician to wait for results obtained by scientific experimentation developed by recognized clinics especially equipped for this type of work.

THE TREATMENT OF EPILEPSY

WILLIAM G. LENNOX, M.D.*

IN the treatment of every disease, increased knowledge about that disease brings new opportunities and added responsibilities for the physician. Chemotherapy, for example, means added years of life for the patient, but also increased reading and study for the doctor. Tragic is the fate of the patient whose doctor has not been able to "keep up" with newly gained knowledge.

In recent years the gains against epilepsy have been as real, in relation to former knowledge, as those against infectious diseases, yet most patients, after visits to many doctors, are bewildered, discouraged, and still convulsing. This need not be. Epilepsy can no longer be classed as a "cause unknown" disease. The physician has at hand therapeutic weapons, both medicinal and social, which were lacking a dozen years ago. By means of the electroencephalograph, he can now look behind the patient's variegated and unpredictable seizures to the disordered electrical pulsations of his brain and thus gain a better insight into the type and extent of the disorder, and more intelligently select the drug most likely to succeed. The half million epileptics in the United States cannot be treated by a few specialists. The average epileptic must look to his own doctor, hoping that this doctor has sufficient interest in him and his problems and sufficient medical knowledge to give him treatment which is not traditional but modern.

Treatment of seizures cannot be instituted until two questions have been considered. First, is this person really epileptic? Second, what conditions in this particular patient are responsible for his seizures?

IS THIS EPILEPSY?

The diagnosis of epilepsy seems disarmingly easy because the word describes a symptom or group of symptoms. Epilepsy is the Greek word for "seizure" so that any one who comes to his physician with the story of repeated sudden loss of consciousness, possibly with accompanying involuntary muscle movements or peculiar actions, is by definition an epileptic. However, by common consent various seizure phenomena have been set aside as nonepileptic. These include syncope, episodes which resemble syncope but are due to an irritable carotid sinus, periods of unconsciousness or amnesia due to hysteria, convulsions which occur in the course of toxemia of pregnancy, or uremia, or which are directly due to hypoglycemia, or to the ingestion

* Assistant Professor of Neurology, Harvard Medical School, Visiting Neurologist, Boston City Hospital, Visiting Physician, Children's Hospital of Boston.

of a convulsant drug Isolated convulsions which occur with fever in childhood are not epilepsy, although they have something like a 10 or 20 per cent chance of becoming so Excluded also are certain conditions which have some superficial resemblance to convulsive episodes but do not possess the cardinal feature of lost consciousness Examples are tetany or spasmophilia, chorea, sudden muscular collapse (cataplexy) which occurs in patients subject to narcolepsy, or inability to move on entering or leaving sleep (sleep paralysis) Strictly defined, localized convulsive movements without loss of consciousness, jacksonian epilepsy, should be excluded.

The diagnosis of epilepsy is made chiefly by exclusion (eliminating each of the above mentioned possibilities through careful history taking and appropriate examinations) In addition, positive evidence may be supplied by the electroencephalograph, when this is available.

In excluding conditions which resemble epilepsy, description of the seizure and of the surrounding events is of prime importance. Syncope almost always occurs when the person is upright, is preceded by symptoms of sympathetic perturbations, is attended by pallor and muscle flaccidity (except for a few clonic jerks) and is not followed by after-symptoms. The carotid sinus syncope is ruled out by failure to produce the syndrome by pressing on the sinus Hysteria is set in an emotional frame, the convulsive movements are bizarre and consciousness is not entirely absent. However, hysterical convulsions or periods of amnesia and psychomotor epilepsy are easily confused Convulsions due to hypoglycemia should occur long after a meal and be preceded by symptoms of hunger, weakness, sweating and fast pulse.

Physical or laboratory examinations may demonstrate disorders of circulation which lead to cerebral anemia, disease of the kidneys with resulting toxemia or disorders of metabolism like hypoglycemia or hypocalcemia. By far the most important laboratory test in differentiating epilepsy from other conditions is the electroencephalogram.

The Epileptic Fit—In diagnosing epilepsy by the description of the seizure, the physician must remember that there is no "typical" fit. Individual seizures are almost infinitely varied Nevertheless certain separations are possible Clinical descriptions or electroencephalographic (E.E.G.) tracings made during seizures permit segregation of epileptic seizures into seven types as in the accompanying table and Figure 162

SEVEN TYPES OF SEIZURES

- 1 *Jacksonian Epilepsy* Convulsive movements, or sensations, which begin in an extremity and spread upward in a "march" while consciousness is retained The seizures may end here, or continue into a grand mal, with loss of consciousness. Electroencephalogram High voltage fast waves begin locally and spread.
- 2 *Focal Fit* A grand mal convulsion which is predominantly or wholly one sided, or with initial turning of the head and eyes to one side, or has a localizing aura such as a peculiar odor Electroencephalogram During a convulsion as in grand mal in free period possibly a focus of very slow waves in area of a lesion, if this is in or near the cortex.

3 *Grand Mal* A convulsion, tonic and then clonic, involving the whole body, with unconsciousness Electroencephalogram Generalized high voltage fast waves

4 *Psychomotor, or Psychic Equivalent Seizure* A period of amnesia with or without tonic spasm or contortion of trunk muscles The person may appear to

Fig 162 —The four different patterns of waves observed during four different types of seizures, grand mal (including jacksonian and focal), petit mal (also called pykno-epilepsy), petit mal variant (in which the association of seizure discharges and clinical symptoms may be vague or absent) and psychomotor In each case the left hand portion of the tracing is the person's normal record *A* and *B* in the bottom tracing represent different stages in this particular patient's seizure The horizontal line at the bottom indicates one second, and the perpendicular lines at the right the signal made by 50 or 200 microvolts of current. (Gibbs, F A., Gibbs, E. L and Lennox, W G Arch Neurol & Psychiat. 41 1111 [June] 1939)

act in a normal manner, or be confused or mutter, make chewing motions, have a "running fit," or become immobile with slow rotation of the body Manifestations are of extreme variety, often leading to the mistaken diagnosis of hysteria The patient has no memory of events during the attack and may be unaware that the attack has occurred

suggesting congenital maldevelopment of the brain, a story of birth injury, of cerebral or meningeal infections, or of certain cerebral diseases of later life, such as trauma, syphilis, tumors, or cerebral circulatory disorders. Second, a description of jacksonian seizures or of aura or convulsive movements confined to one side of the body. Third, neurological signs indicative of cerebral pathology. Fourth, laboratory evidence of cerebral pathology derived from roentgen rays of the skull or of the ventricular system (pneumoencephalogram) or from the electroencephalogram. In appraising the etiologic importance of brain pathology, the damage must have antedated the epilepsy, and not be merely the result of subsequent falls or convulsions.

The Electroencephalogram—Much the most important tool for determining the diagnosis, and the causes of seizures, and in guiding treatment is the electroencephalograph. Unfortunately this technic will only slowly become generally available. The apparatus is expensive and some widely advertised types are wholly unreliable. The making of satisfactory records and their proper interpretation requires even more experience and skill than the electrocardiograph. Artifacts may be confusing, the frequency and voltage of waves are modified by activity of brain or body or by sharp alterations in body chemistry, hence records must be made under standard conditions. However, the cost and trouble involved in obtaining dependable brain wave tracings is as nothing compared with the cost of epilepsy and the difficulties of treating it without the aid of this technic.

As with most other laboratory devices the electroencephalogram supplements but does not supplant diagnoses made from the description of seizures. The significance of a record varies with the degree of its abnormality. In a group of 1260 patients diagnosed as epileptic on clinical grounds, in 13 per cent the electroencephalogram was considered normal, in 29 per cent the waves were only moderately slow or fast, and hence weakly support a diagnosis made on clinical grounds, in 20 per cent waves were very slow or fast, and hence suggestive of epilepsy. In 38 per cent there were paroxysmal discharges of high voltage fast or slow waves, which are strongly suggestive of epilepsy. Half of these records with seizure discharges (19 per cent of all patients) were of the alternating dart and dome formation, which is diagnostic of petit mal.

The relative significance of various patterns is shown by their distribution in 730 adult epileptics, and in 1260 "normal" persons. Thirty-three of the epileptics had tracings with bursts of high voltage waves (seizure discharges) for each nonepileptic with this sort of tracing. The corresponding ratio for tracings with very slow or very fast waves of usual voltage was 20 to one, and for tracings with mildly slow or fast waves the ratio was two to one. For normal tracings the ratio was one in the epileptic group to six in the normal group.¹ In addition to giving substantial confirmation of the diagnosis in one-half

or more of cases, the electroencephalogram usually furnishes a clue as to the severity of the condition, a relatively normal record presumably carrying a good prognosis. The examination may also point to a localized cortical lesion, and may indicate the success of therapy, for the goal of treatment is to cure not only the seizures but also the associated cortical dysrhythmia. Finally, as a hereditary trait, recordings of the brain waves may help in tracing the heredity of epilepsy and in advising about marriage and children.^{2 3}

FOUR FRONTS OF FREEDOM

Epilepsy needs to be attacked from all possible directions. Four of these have well defined possibilities: general hygiene and diet; neurosurgery, drug therapy, and social-psychological therapy.

General Hygiene and Diet—Maintenance of a good physique, avoidance of physical exhaustion and regularity of living are desirable goals. Aside from the correction of any specific abnormalities of function discovered in the physical examination, only common-sense rules need to be adopted. These refer to good posture, normal functioning of the digestive tract, regularity in habits of eating and sleeping, attention to proper exercise and recreation, and maintenance of a vigorous musculature. These are small items, but in the total reckoning are not above the attention of even the busiest of doctors. The diet should be adequate, but need not be specified unless constipation or other disturbance of function is present. In children a high fat, low carbohydrate (ketogenic) diet has often proved useful, especially for the control of petit mal. Wartime rationing increases the usual difficulties encountered in administering this diet. Limitation of fluids (the dehydration treatment) has also been advocated, but is also difficult of execution and in effectiveness falls far behind the use of drugs.

Surgical Treatment.—Only rarely is the evidence from a history of injury, of focal convulsions, or from pneumo- or electroencephalograph sufficiently strong to justify exploratory operation on the brain. Jacksonian seizures are more likely to call for operation than focal seizures. The most hopeful cases are slow-growing or cystic tumors, or scars involving the cortex, which are associated with localized rather than generalized cortical dysrhythmia. The chances of successful removal of a lesion and the nearby nerve cells which form a focus of abnormal discharge must be weighed against the danger of the procedure and the chances of a residual paralysis. Patient location of the trigger point by electrical exploration of the cortex and clean dissection is essential for success.

Whether exploration is urgent or not depends on the suspected pathology. Delay in removing a tumor may imperil life. Scar tissue, the result of severe trauma or penetrating gunshot wound, should be excised early for, according to Penfield, the area of gliosis at the periphery of a cicatricial area tends to extend for years. Simple separation

of adhesions between the brain and meninges, or tying redundant blood vessels is of little or no avail. With careful selection of cases and expert surgical technic (plus postoperative use of drug therapy) the removal of cortical scars or superficial tumors may result in virtual freedom from seizures for as many as two-thirds of the patients. Any one contemplating neurosurgical attack on epilepsy should study the book by Penfield and Erickson.⁴

Drug Therapy.—The chief hope of controlling seizures lies in improving the chemistry of abnormally discharging nerve cells, through the administration of medicine. The physician now has a number of drugs from which to choose. Good results from treatment depend on discrimination in the choice of these and skill in determining the dosage best suited to the individual patient. No medicine should be continued unless adequate trial demonstrates that seizures are fewer or less severe with than without it. "Adequate trial" means daily use over months of time of each of the most effective drugs, each given in increasing amounts until either toxic symptoms appear—or seizures disappear. After two or three years of freedom (and an improved electroencephalogram) medicine may be stopped.

First we shall describe the various drugs and later discuss their choice.

Bromides, a phenomenal discovery when first used in 1857, are gradually assuming a place of historical importance only. For most patients they are the least effective of the anticonvulsants and, when given in considerable amounts, may cause unpleasant acneform eruptions and impair mental alertness. In order to maintain a certain level of bromide in the body, the chloride intake needs to be kept constant. A usual dose is 10 to 20 grains (0.6 to 1.2 gm) of sodium or potassium bromide given three times a day in a watery solution.

Phenobarbital has been in use since 1912. It is also sold under the trade name of luminal at a considerable increase in price. Phenobarbital has the advantage of being easy to administer. After the optimum dose has been ascertained, patients may continue treatment for months or years with little supervision. The side-effects of this drug are a scarlatina-like generalized rash, in the rare person who is allergic to it, or loss of mental alertness if the dose proves excessive. Individual reactions vary widely. Some patients experience uncomfortable drowsiness with as little as one-half grain a day, whereas other patients can take as much as six or eight grains without noticeable effect. The drug may be used daily for many years without ill effect and without the establishment of habit. The amount may need to be increased from time to time. When taken in huge amounts by mistake or in suicidal attempts, the person experiences extreme ataxia and deep sleep amounting to coma. Phenobarbital is dispensed in tablets containing $\frac{1}{4}$, $\frac{1}{2}$ or $1\frac{1}{2}$ grains (0.015, 0.03 or 0.1 gm). For daily oral use the average adult dose is $1\frac{1}{2}$ grain (0.1 gm) which may be divided between

morning and evening or taken as a single dose at bedtime. The principle is to build up a certain concentration in the body. The drug is excreted slowly, so that frequent divided doses are neither essential nor oftentimes desirable.

Phenytoin sodium (sodium diphenylhydantoinate) is an American discovery, first used by Putnam and Merritt of Boston in 1938.⁶ A trade name is *dilantin sodium*. This compound, unlike the other two, has little hypnotic effect. On the other hand, administration and dosage require careful supervision because the dose giving full therapeutic effect may approach that at which unpleasant side-effects appear.

The side-effect most frequently encountered is muscular incoordination, expressed as nystagmus, or double vision, unsteadiness in gait, or giddiness. There may also be gastric distress (for which an enteric-coated capsule is available). Two or 3 per cent of patients, those who are allergic to the drug, have a measles-like rash or even a hemorrhagic eruption. Skin eruptions require prompt discontinuance of the drug, though if the skin reaction is mild, gradual reinstatement is often possible. Enlargement of the gums, a frequent complication in children, is not due to vitamin deficiency and can only be minimized by strict oral hygiene and frequent massage of the gums. Overgrowth of hair is seen occasionally in adolescent girls. Rarely there may be loss of weight, drowsiness, fatigue, increased activity, or psychotic-like episodes. The reason for these symptoms in isolated instances has not been demonstrated nor has there been satisfactory explanation for the fact that phenytoin sodium is not equally useful in all types of seizures.

The potentialities of phenytoin sodium have not been fully realized because many doctors suppose that the dosage is similar to that of phenobarbital or they fear side effects. Phenytoin (*dilantin*) sodium is dispensed in sealed capsules containing either $\frac{1}{2}$ or $1\frac{1}{2}$ grains (0.03 or 0.1 gm.) For adults the beginning dose is a $1\frac{1}{2}$ grain capsule taken two or three times a day with meals (and with plenty of water in the event there is gastric distress). The dose is then increased gradually at two- or three-month intervals until either seizures are controlled or unpleasant side effects appear. The dose is maintained at a level which is most effective or is just below the level of unpleasant symptoms. For adults this is three, four or five $1\frac{1}{2}$ grain (0.1 gm.) doses daily, and for young children a third of that amount. Use over a period of years has not resulted in reported ill effects nor, in general, has there been failure of the drug to hold vantage points which were gained initially. As with phenobarbital, the dosage may need to be increased if the seizures return. For patients who do not experience gastric distress two or more capsules may be taken together for the sake of convenience. When the maximum dose of phenytoin which can be borne, is still not effective, the addition of phenobarbital gives additional benefit in approximately one third of the cases.⁶ Such addition, however, does not permit reduction in the amount of phenytoin.

Mebaral (n-methylethyl-phenyl barbituric acid), in Europe called prominal, is sometimes used as a substitute for phenobarbital.⁷ Dispensed in tablets of $\frac{1}{2}$ and 3 grains (0.03 or 0.2 gm) from 3 to 9 grains (0.2 to 0.6 gm) may be given daily.

Amphetamine (benzedrine) *sulfate* has been advocated in order to offset the sedative effect of anticonvulsants which are hypnotic, or perhaps when alcoholism, behavior or narcolepsy is a complication. The dose is from 5 to 30 mg a day, taken mostly in the forenoon to prevent insomnia.

Caffeine can be taken as pills or more pleasantly as coffee, counting 2 grains to the cup. Dosage varies from 5 to 15 grains a day taken with meals. If too stimulating, or if definite results are not observed quickly, large dosage should not be maintained.

Glutamic acid is dispensed in large 5 grain (0.33 gm) tablets. The dose per day is 36 tablets (12 gm). The amount is usually limited by gastric distress, allayed somewhat by liberal use of fluid.⁸

Tridione (3, 5, 5-trimethyloxazolidine-2, 4-dione, Abbott), described by Richards and associates,^{9, 10} is not yet on the market, and will be mentioned under "petit mal."

Other drugs, some of considerable promise in animal observations, are now receiving clinical trial. The report of Merritt¹¹ indicates the range which has already been covered.

Different Drugs for Differing Seizures—For many years quinine was given for all sorts of fever. Now a certain drug is aimed at the cause of the given fever. When only the sedatives bromide and phenobarbital were available, of necessity one of these was given for all types of seizures, whether convulsive or not. Other medicines are now at hand. We know that different kinds of seizures are associated with different wave frequencies (see the figure) and that these frequencies are affected in opposite ways by opposite alterations of brain chemistry. Logically, therefore, a specific chemical should be chosen for the stabilization of specific cortical dysrhythmias and for specific types of seizures. Essential knowledge for doing this is still lacking and we must for the present depend on the method of trial and error. Each case is a therapeutic experiment. Open-minded individuality of treatment is a cornerstone of success. However, much time and grief can be saved by an understanding of which drug is most likely to affect favorably a certain type of seizure.

JACKSONIAN AND FOCAL SEIZURES—In spite of the successful surgical removal of an epileptogenic lesion, supplementary drug therapy may be required. *Phenytoin sodium* is the drug of choice, followed by phenobarbital and bromides. Because pathologic involvement of the brain is present, doses larger than average will be required.

GRAND MAL—Here again *dilantin sodium* is the drug of choice, then phenobarbital, mebaral or bromides. If the case is a "fresh" one, and

immediate control of seizures is not essential, phenobarbital is used first because of the ease of handling and the relative infrequency of side effects

Control of status epilepticus (repeated convulsions) imposes particular difficulties. The patient is of course in bed and, if the condition has persisted more than six or eight hours, he has been given a cleansing enema and is receiving normal saline or 5 per cent glucose solution intravenously. As for anticonvulsants, 3 grains (0.2 gm) of soluble phenobarbital (sodium luminal) dissolved in 10 cc. of water may be given parenterally three or four times in twenty-four hours. Long-lasting narcosis must be avoided. Paraldehyde has the advantage of brief action. From 4 to 8 cc. are injected intramuscularly or very slowly intravenously, stopping when cyanosis appears. If exhaustion threatens, the force of convulsions can be blunted by etherization or possibly by injection of curare (the last named is still experimental and is not here recommended).

PSYCHOMOTOR SEIZURES—*Phenytoin sodium* is not only the best drug, it is for most patients the only one for this type of seizure and is to be used without preliminary trial of phenobarbital. The latter drug, given in large amounts, in some cases seems actually to induce or prolong the amnesic or psychotic-like episodes. If the patient proves sensitive or allergic to the drug, or if it doesn't control, phenobarbital should be tried, perhaps with the addition of amphetamine (benzedrine) sulfate to combat drowsiness, if the required dose of phenobarbital is large.

PETIT MAL, MYOCLONIC JERKS AND AKINETIC SEIZURES—These three manifestations may be grouped together since in each the cortical dysrhythmia, when present, is of the alternate wave and spike variety. However, persons, usually children, with akinetic seizures are more likely to have the slower, two per second formation in the routine record. This, unlike the three per second variety, is not easily influenced by alterations of blood alkalinity, carbon dioxide, glucose or oxygen. Also, the akinetic seizures more often have a background of pathology than the petit mal.

The *ketogenic diet* is of definite value in many cases of petit mal. Phenytoin sodium may increase petit mal, and only the occasional patient with one of these three forms of epilepsy is helped by phenytoin sodium, phenobarbital or mebaral, although each of these drugs is worth a trial, in order to discover that occasional patient.

In a minority of patients I have observed beneficial results in petit mal or myoclonic jerks from the daily administration of 10 to 15 grains of *caffeine* without other therapy. Most patients, however, either are not helped or are too stimulated to continue. Most striking has been the case of one young man with myoclonus epilepsy whose jerks are so frequent and violent that for years he has been unable to

work on those days in which he does not drink from five to ten cups of coffee. Intravenous injection of 0.5 gm. of caffeine sodium benzoate stops at once both the jerks and the wave and spike formations of the electroencephalogram.

Price, Waelsch and Putnam⁸ in 1943 reported six cases of petit mal and two of psychomotor seizures in which the addition of *dl*-glutamic acid to the patient's other medication improved both the seizures and the dispositions of patients. At first the authors believed benefit was due to an acidifying action of the drug, but later experience disproved this. Until results on a larger series of cases, and by other authors are reported, glutamic acid must remain as another "something that might be tried."

Amphetamine (benzedrine) sulfate has received favorable mention in the treatment of petit mal in children.

Tridione (3, 5, 5-trimethyloxazolidine-2, 4-dione, Abbott) in my experience has had the most decisive inhibitory effect on petit mal (pykno-epilepsy), myoclonic jerks and akinetic seizures of anything so far tried. The experience has been too short to judge of the long-term effects, either in stopping seizures or in producing unpleasant side effects. Also, the medicine cannot be ready for the market for some time.

I have given this drug to thirty patients who were having petit mal (pykno-epilepsy) very frequently, five to fifty attacks daily, which had not been helped by one or the other of dilantin, of phenobarbital or of glutamic acid. Because petit mal recurs many times a day the immediate results of therapy can be seen quickly, but in judging effects caution is required because of the fact that petit mal tends to disappear spontaneously before adulthood is reached. These thirty patients have taken tridione for a period of from one to twelve months. Petit mal, myoclonic jerks or akinetic seizures have disappeared or practically disappeared in two-thirds. Nearly all experienced some improvement, but in some the intervention of side effects (skin eruptions, nausea or sensitiveness to light) prevented continued use. An unexpected, but welcome, feature in several cases has been the failure of seizures to return after the drug was discontinued. These observations on the effect of 3, 5, 5-trimethyloxazolidine-2, 4-dione on the three types of seizures are only preliminary, and are mentioned here principally to illustrate the point that drug therapy in epilepsy is a fertile field which has not yet been adequately tilled.

MIXED SEIZURES—The patient who has both grand mal and petit mal presents a dilemma, for the best remedy for grand mal (phenytoin sodium) may aggravate petit mal. In the presence of grand mal, petit mal may be disregarded and phenytoin sodium prescribed, phenobarbital may straddle the dilemma, or a combination of phenytoin sodium and one of the drugs effective for petit mal may be tried. Only patient testing will give the right answer for the individual patient.

This section on therapy may end with mention of the most potent of remedies, that supplied by nature. Brain waves become more stabilized, seizures tend to become fewer as the person grows older.

Social and Psychological Treatment—The physician who examines and prescribes medicine for his epileptic patient has discharged only half of his responsibilities. Efforts to control attacks are indeed the substantial core of the treatment, but attention must be paid to the doubts and fears which both possess and surround the patient: fear of the seizure, which strikes without warning, fear of what people will say, of losing his friends and his job, of losing his mind, of never losing these horrible convulsions. First the patient must be "strengthened in the inward man," given perspective, hope, courage and the will to win. Parents, family and friends must be coached as to the proper measures and attitudes: quiet and frank helpfulness without show of undue anxiety or the imposition of unnecessary restrictions, but with assistance in gaining an education and in maintaining employment and normal social relationships. A popular exposition of the essential facts about epilepsy and its treatment is in book form.¹²

The physician must evaluate the strength of the materials with which he has to build. Some patients are carefree to the point of neglecting medication and are impervious to the implications of their condition. Others who may be much more lightly affected are so discouraged and burdened with fear and shame that words of hope fall on thickened eardrums. Parents may be selfish and thoughtful only of their own convenience and social position or they may be overfearful and solicitous to the point of neutralizing the best efforts of the doctor. In most cases parents and other relatives are sufficiently intelligent and cooperative so that a forward-looking program can be carried out. In a well ordered hospital or clinic, social workers are of great help. Treatment of the whole person and not just his seizures is expensive of time, but in the end rich rewards accrue to the physician who counts his income in grateful friends as well as in dollars. Physicians who follow their patients from youth into manhood and womanhood, as I have, will realize with relief that time is on the side of the patient, that seizures tend to get better, rather than worse, with the passing years.

The further one gets from the family circle the more difficult are the adjustments. Children of school age encounter ignorance and prejudice among teachers and the parents of other students. Parents must make contact with principal and teachers and secure their cooperation, backed if necessary by a note from the doctor. Continuance in school when attacks are infrequent, is a part of the treatment for most youngsters. The exceptional child who is overconscientious or excitable or nervous about his work may need to be taught at home.

Exercise of the mind is as important a therapeutic agent as many of the drugs in common use. Activity of nerve cells results in production

TYPES OF SEIZURES, ELECTROENCEPHALOGRAPHIC PATTERNS AND THERAPY

Type of Seizure	Chief Characteristic	Electroencephalogram		Therapy In Order of Choice
		In Seizure	Interseizure	
Jacksonian	"March" of sensation or motion, consciousness retained	High voltage fast discharge beginning locally and spreading	Usually normal.	Surgical removal of discharging focus Phenytoin sodium. Phenobarbital or others.
Focal convulsion	One-sided convulsion or localized symptoms initiating generalized convulsion—consciousness lost	High voltage fast waves beginning locally	Focus of seizure discharge or swaying baseline.	Possibly neurosurgery Phenytoin sodium. Phenobarbital or others.
Grand mal	Generalized tonic-clonic convulsion, consciousness lost	Generalized continuous high voltage fast waves or spikes	Seizure discharge—17% Waves slow or fast—64% Normal—18%	Phenytoin sodium. Phenobarbital or others.
Psychomotor (psychic equivalent)	Period of amnesia, with or without tonic muscular spasm or contractions	Generalized high voltage slow waves, perhaps square topped.	Seizure discharge—49% Waves slow or fast—36% Normal—15%	Phenytoin sodium
Petit mal (pykno-epilepsy)	Transient lapse of consciousness, minimal rhythmic jerking at three per second	Generalized high voltage dart and dome at 3 per second	Dart and dome—82% Other abnormalities—10% Normal—8%	Ketosis Tridione, Caffein Glutamic acid Mebal or others
Myoclonic jerks	Lightning like jerk of extremities, with consciousness probably retained.	If anything, single petit mal dart and dome	Possibly isolated dart and dome	Same as for petit mal
Akinetic	Sudden loss of posture with falling or nodding	Often series of high voltage 2 per sec. slow spike and wave—frequently localized—pronounced dysrhythmia and oftentimes not accompanied by clinical symptoms.		Tridione Phenobarbital or others

of carbon dioxide and acidosis which tends to inhibit the abnormal electrical discharges which are the inward expression of observable seizures. For practical reasons also education and training are assets which tend to counterbalance the liability of seizures.

For those beyond school age, employment is important not only for the individual and society, but also for maintenance of morale and for its anticonvulsant influence. Muscular and mental activity is a therapeutic agent, a fact which needs to be continuously reiterated because for generations the dictum has been "quiet and rest."

The physician also has responsibility for the education of fellow physicians and the general public. He should encourage many of his patients to join the American Epilepsy League which has its headquarters at 50 State Street, Boston. By joining with others similarly situated, the patient and his family and friends can aid in the important task of breaking down public prejudice, and in encouraging the medical research which is essential for continued gains against epilepsy. Physicians who have a continuing interest in this subject should also join the American Chapter of the International League Against Epilepsy* which, jointly with the American Epilepsy League, publishes the magazine, "Epilepsia." The broader and more numerous the fighting points established against epilepsy the sooner will it be conquered.

CONCLUSIONS

Epilepsy is no more enigmatic than diabetes or extrasystoles or old age. Sometimes neurosurgery, and always mental hygiene, are important aids to treatment, but success depends much on skill and individuality in the administration of drugs. Epilepsy is a chemical disorder to be treated in the main with chemical means. The different types of seizures—jacksonian, focal, grand mal, psychomotor petit mal (pykno-epilepsy), myoclonic and akinetic—may require different surgical or medical treatment. A new medicine, tridione, which is not yet on the market, promises help for most patients whose seizures are of the petit mal (alternate spike and wave) variety. Most patients who are treated as individuals, with consideration for the type of seizure and for the complicating psychological and social problems can be made relatively free of seizures and of fear.

THE TREATMENT OF NONHEMOLYTIC STREPTOCOCCUS SUBACUTE BACTERIAL ENDOCARDITIS WITH PENICILLIN

DONALD G. ANDERSON, M.D. * AND CHESTER S. KEEFER, M.D., F.A.C.P. †

UNTIL very recently, few diseases have presented a more hopeless prognosis than has subacute bacterial endocarditis. Prior to the introduction of the sulfonamides no effective treatment was known and the mortality rate exceeded 99 per cent. It is now recognized that the advent of sulfonamide therapy marked the beginning of a new era in the treatment of this disease. For the first time, adequate evidence was provided that this disease could be cured by the administration of a specific chemotherapeutic agent. Unfortunately, the number of patients permanently benefited by sulfonamide therapy was disappointingly small, since not more than 5 per cent of all those treated recovered. Thus, while the sulfonamides established the principle that subacute bacterial endocarditis could be cured, the need for an even more potent chemotherapeutic agent for the treatment of this disease soon became clear.

During the last year and a half experience has been accumulating to indicate that in penicillin a chemotherapeutic agent is now available that will make possible the successful treatment of approximately 75 per cent of patients with subacute bacterial endocarditis caused by nonhemolytic streptococci. At this time we propose to review some of our experiences with the use of penicillin in the treatment of this disease. Before taking up the problem of treatment, however, we shall review briefly the more important facts that are known concerning the incidence, etiology, pathogenesis, and clinical course of subacute bacterial endocarditis.

Incidence—Subacute bacterial endocarditis is not a rare disease. Post-mortem studies have shown that approximately 25 per cent of all adult patients with rheumatic heart disease die of it. The incidence of the disease in patients with congenital anomalies of the heart and

From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston. The penicillin was provided by the Office of Scientific Research and Development from supplies assigned by the Committee on Medical Research for clinical investigations recommended by the Committee on Chemotherapeutics and Other Agents of the National Research Council.

great vessels is probably at least as high. In any moderate-sized hospital with an active medical service in areas where rheumatic heart disease is prevalent, it is not unusual to encounter annually at least five or ten patients suffering from this disease.

Etiology—It is well known that this disease is usually caused by organisms of low virulence. The organism encountered in about 95 per cent of all cases is the nonhemolytic streptococcus, various species of which are normal inhabitants of the oral cavity and the gastrointestinal tract of man. Many of these species produce a greenish discoloration when grown on blood agar. Such organisms have been commonly referred to as streptococcus viridans (alpha hemolytic streptococci). Other species produce no alteration in the blood and have been termed indifferent streptococci (gamma streptococci). Rosebury has reviewed the recent attempts to arrive at a more precise classification of nonhemolytic streptococci, and his article may be profitably consulted by those who are interested in this problem.

Occasionally other organisms of low virulence are found to be the cause of subacute bacterial endocarditis. Included in this group are *Hemophilus influenzae*, the various members of the *Brucella* group, the members of the genus *Neisseria*, *Staphylococcus albus*, and *Streptobacillus moniliformis*.

Predisposing Factors—With rare exceptions, subacute bacterial endocarditis occurs only in patients with preexisting valvular heart disease. Thus, about 80 per cent of cases occur in patients with rheumatic heart disease. It is well known that patients who have had only one or two attacks of acute rheumatic fever, who have never suffered from marked congestive heart failure, and who have not developed auricular fibrillation are the rheumatic subjects most likely to develop subacute bacterial endocarditis. There seems little doubt that the acquiring of this disease is an accident that significantly shortens the life of just those patients with rheumatic heart disease who might otherwise have the best prognosis for longevity. The studies of Juca and White have demonstrated that the interval between the first attack of rheumatic fever and death is shorter in patients dying of subacute bacterial endocarditis than in any other group of adult patients with rheumatic heart disease.

Next in order of frequency the disease is encountered in patients with congenital anomalies of the heart or great vessels. Occasional cases are seen in which the preexisting valvular lesion is due to syphilitic involvement of the aortic valve, even less common are cases in which the only abnormal changes in the valves are those due to atherosclerosis.

Perhaps the best explanation as to why this disease occurs almost entirely in patients with preexisting valvular lesions is that advanced by Grant. By means of careful postmortem studies he demonstrated that minute platelet and fibrin thrombi can usually be detected on the

surface of the heart valves of patients with rheumatic and congenital valvular lesions. Normal valves, on the other hand, rarely show these thrombi except in an occasional patient who has undergone a long, debilitating illness. Grant postulated that such fibrin thrombi serve as a focus in which bacteria that gain transient access to the blood stream may become lodged and multiply and thus give rise to a typical bacterial vegetation. In normal hearts bacteria find no such prepared lodgment, and as a result they are eliminated by the normal antibacterial activity of the blood without having an opportunity to gain a foothold and multiply.

Pathogenesis—When the predisposing factors mentioned in the preceding section are present the critical point in the pathogenesis of subacute bacterial endocarditis becomes the mechanism whereby bacteria gain access to the blood stream and thus secure the opportunity to localize on the heart valves. It is now appreciated that transient, asymptomatic bacteremias are much commoner than was once supposed. Thus, it has been demonstrated that in the first five minutes after tooth extraction in 15 to 70 per cent of patients various organisms, most frequently nonhemolytic streptococci, can be cultured from the circulating blood. The poorer the condition of the patient's gums the more likely is bacteremia to occur. Simple massage of the gums or vigorous mastication may at times be sufficient to give rise to bacteremia. After tonsillectomy, after abdominal operations, or after manipulative procedures involving the genitourinary tract transient bacteremia may also be detected, although with less frequency.

Once attention was directed to the possible role that such episodes might play in the pathogenesis of the disease, it was not long before physicians began to report cases of subacute bacterial endocarditis in which the onset of the disease could be definitely associated with one of the precipitating incidents that have been mentioned. Careful history taking has revealed that in no less than 25 per cent of patients who develop subacute bacterial endocarditis the onset of symptoms follows closely the extraction of one or more teeth. In a smaller group of patients, the disease has been shown to follow other operative procedures or uncomplicated upper-respiratory infections. While our knowledge of the precipitating factors is increasing, it must be acknowledged that in more than half the patients with subacute bacterial endocarditis even the most careful history fails to reveal the initiating injury that produced the bacteremia.

Clinical Manifestations—The symptomatology of subacute bacterial endocarditis is essentially that of a chronic infection, the gradual downward course of the illness being punctuated from time to time by embolic episodes of lesser or greater magnitude. The duration of the disease varies from a few weeks to more than a year. The average duration in untreated cases is approximately six months.

The classical picture presented by a moderately advanced case is a

familiar one and is easily recognized. The patient is listless and wasted. There is fever, usually of the remittent type, and night sweats may be severe. Pallor is marked. Clubbing of the fingers and toes is common. Petechiae are found in the conjunctivae, ocular fundi, oral mucosa, and skin. Osler's nodes may be present, as well as splinter hemorrhages beneath the nails. The examination of the heart almost always reveals the signs of antecedent valvular disease. The spleen is usually palpable. Embolism produces severe pain or marked disturbances in function of the involved part.

Such well known manifestations of the disease require no special comment. During the early weeks of the infection, however, the pathognomonic stigmata of subacute bacterial endocarditis are frequently absent, and Christian has recently directed attention anew to the fact that the presenting symptoms during the early phase of the disease may be quite nonspecific. In reviewing a large series of cases, he found that in 52 per cent the earliest symptoms were malaise and fever, in 32 per cent joint or muscle pains, and in 16 per cent nausea or loss of appetite. In the majority of these cases the correct diagnosis was not made until the disease was moderately far advanced. Among the incorrect diagnoses that were entertained for longer or short periods were those of influenza, grippe, typhoid fever, tuberculosis, undulant fever and acute rheumatic fever.

Christian has rightly urged that in any patient with valvular heart disease who has fever lasting more than one week that has not been fully explained, the diagnosis of subacute bacterial endocarditis should be strongly suspected and a blood culture be obtained.

Complications—The complications of the primary disease that may occur in subacute bacterial endocarditis are too numerous to be reviewed in detail. Large emboli may seriously impair the function of any organ. Three important complications may be briefly mentioned. The implantation and subsequent proliferation of bacteria on the walls of the large or small arteries may occur and result in the production of *mycotic aneurysms*. Such aneurysms may rupture and give rise to a fatal hemorrhage.

Pathologic changes in the kidney are encountered with great regularity. Usually the lesion is of the focal embolic type and has no significant effect on renal function. In 10 to 20 per cent of cases, however, a true *diffuse glomerulonephritis* develops, and in such instances signs of impaired renal function appear and the patients not infrequently die in uremia. For reasons that are not at present clear, this complication is most apt to occur in so-called "bacteria-free" cases.

A *diffuse myocarditis* apparently due to the embolization of the small branches of the coronary arteries may occasionally be present, and if extensive may give rise to the development of severe congestive heart failure. Although not an actual complication of the bacterial infection, it should be recalled that acute rheumatic myocarditis also

may and frequently does exist concomitantly with subacute bacterial endocarditis

Diagnosis.—The diagnosis of subacute bacterial endocarditis is most firmly established by culturing the infecting organism from the blood. In patients who present typical clinical findings two positive blood cultures may be considered sufficient to substantiate the diagnosis. In more obscure cases the diagnosis is made with more certainty when the same organism is recovered in three or more cultures.

In 85 to 90 per cent of cases the physician can recover the organism from the blood without difficulty. Incubating the cultures in an atmosphere containing an increased concentration of carbon dioxide often facilitates the growth of nonhemolytic streptococci. A simple candle jar will usually provide a sufficiently high carbon dioxide concentration for this purpose.

In 10 to 15 per cent of cases, however, it is well known that repeated cultures of the blood fail to reveal the presence of organisms, although bacteria can be readily cultured from the vegetations on the valves at autopsy. Such cases have been called "bacteria-free" cases. Two explanations have been advanced to account for the failure to recover the organisms from the blood during life. One is that the high antibody titer of the blood that is usually present in this disease results in the death of the bacteria as soon as they are swept out into the circulating blood, the organisms that remain in the vegetations being protected from the bactericidal action of the blood by the surrounding meshwork of fibrin. The other explanation for the occurrence of "bacteria-free" cases is that the organisms that are liberated from the vegetations are so few that they escape detection in the blood culture.

In "bacteria-free" cases the diagnosis must be made from the clinical findings. It is important that this necessity be recognized, since otherwise such cases may be deprived of effective treatment.

GENERAL CONSIDERATIONS REGARDING PENICILLIN THERAPY

Susceptibility of Nonhemolytic Streptococci to Penicillin.—It is well known that penicillin is selective in its antibacterial action, being quite potent against certain organisms and having little or no effect against others. As in other infections penicillin can be expected to be effective in the treatment of subacute bacterial endocarditis only when the infecting organism is susceptible to the action of the drug.

Fortunately, it has been shown that most species of nonhemolytic streptococcus are susceptible to penicillin. More than 90 per cent of the organisms so far tested have been completely inhibited in vitro by concentrations of 0.1 unit or less of penicillin per cubic centimeter. It should be noted, however, that enterococci have usually shown a high degree of resistance to penicillin and may not be inhibited by concentrations of penicillin of five units or more per cubic centimeter.

Mechanism of Action—In the treatment of disease, therapy is most effective when the precise mechanism whereby an agent effects recovery is understood. Such knowledge makes possible the planning of a rational program of treatment. Our understanding of the manner in which penicillin acts in subacute bacterial endocarditis is still incomplete.

Two possible mechanisms of action may be suggested. One of these takes into account the natural tendency toward the organization and fibrosis of vegetations that is observed even in untreated cases of subacute bacterial endocarditis. It is possible that the prolonged administration of penicillin in adequate doses inhibits the growth and multiplication of bacteria on and near the surface of the vegetations, while granulation tissue growing up from the base of the vegetation and endocardium growing over its surface result in healing of the lesion. It is conceivable that if healing occurs in this manner, the "healed" lesion may contain bacteria that remain viable for a period of time but are well walled off and therefore incapable of causing further injury.

Such a mechanism is in accord with the observed clinical fact that although treatment with penicillin in most cases of subacute bacterial endocarditis renders the blood culture sterile within twenty-four to forty-eight hours, if treatment is not continued for a period of weeks, the blood culture again becomes positive within a short time after penicillin is withdrawn.

The second possible mechanism that can be suggested is that penicillin penetrates all parts of the vegetation and sterilizes the lesion by killing all bacteria present. In support of this mechanism evidence can be advanced that high concentrations of penicillin *in vitro* have a bactericidal action. The dosages usually employed in the successful treatment of subacute bacterial endocarditis, however, do not provide concentrations of the drug sufficiently high to produce such an action. Even if such large doses were used, it is doubtful that the drug could penetrate the dense masses of fibrin commonly encountered in vegetations.

While it cannot be denied that this second mechanism may at times be operative, since clinical experience with the administration of very large doses of penicillin over short periods of time has been limited, the observations to date indicate that the inhibition of the organisms present in the vegetations for a period of time sufficient to permit the organization and endothelialization of the lesion is the more likely explanation for the manner in which penicillin effects recovery in subacute bacterial endocarditis.

General Outline of Treatment—Because not all species of nonhemolytic streptococcus encountered in subacute bacterial endocarditis are sensitive to penicillin, it is important at the outset of treatment to test

each patient's organism for its sensitivity to the drug. This test can be easily performed by a slight modification of the method described by Rammelkamp and Maxon.

In this procedure, a standard solution of penicillin containing 20 units per cubic centimeter is prepared by suitably diluting one of the preparations of penicillin that are available for therapeutic purposes. Fifteen small sterile test tubes are placed in a rack and into each tube 0.5 cc. of nutrient broth is pipetted. To the first tube 0.5 cc. of the standard solution is added, and after thorough mixing serial dilutions are made in the usual manner.

The inoculum of the organism to be tested is prepared by diluting a twenty-four hour culture so that the inoculum contains between 10,000 and 100,000 organisms per cubic centimeter. After the dilution has been made, defibrinated horse or rabbit blood is added to give a final concentration of 1 per cent. Five tenths of a cubic centimeter of the inoculum is then pipetted into each test tube. The tubes are shaken well and incubated for eighteen to twenty-four hours, at the end of which time the tubes are examined for gross evidence of growth. Subcultures are made on blood agar from several tubes near the end point—that is, the tube with the lowest concentration of penicillin that shows no growth.

The test is read by determining the tube containing the least penicillin in which no growth is obtained on subculture. The amount of penicillin in this tube represents the minimum concentration of penicillin per cubic centimeter that will just completely inhibit the growth of the organism tested.

This simple test can be performed by any bacteriologic laboratory. Since its performance requires a minimum of seventy-two hours after the organism has been isolated from the blood culture, the physician may prefer to begin treatment once the diagnosis has been established and later make such modifications in dosage as the results of the sensitivity test indicate.

Dosage.—Clinical experience has demonstrated that in patients whose organisms are inhibited by 0.1 unit or less of penicillin per cubic centimeter a daily dosage of 200,000 units is usually adequate. However, now that penicillin is freely available, it appears to be safer to use a slightly higher dosage, although in most cases there seems to be little reason to increase the dosage beyond 300,000 units a day. In patients whose organisms are less sensitive to penicillin considerable experimentation is frequently necessary to find a dosage that will sterilize the blood.

Methods of Administration.—While we have employed various methods of administration, it is our present belief that the *intermittent intramuscular method* is the most satisfactory and convenient one. When this method is used, the total daily dose is divided into equal doses that are given every two or three hours throughout the day and night. By using a penicillin solution of high concentration—for example, 25,000 units per cubic centimeter—the volume of the individual doses can be kept small and the discomfort caused by the injections be reduced to a minimum.

We have also employed continuous intravenous and continuous in-

intramuscular infusions in our studies. At the moment we do not believe that they offer any particular advantage. They are difficult to regulate, and necessarily result in a certain degree of immobilization of the patient.

Duration of Treatment.—From our experience it is our belief that treatment should be continued for a minimum of two weeks and preferably for three after the blood culture has become sterile. In a few cases more prolonged treatment has been necessary. In such cases it has been our feeling that either the size of the vegetations or peculiarities in the histology of the lesions have produced a delay in organization and endothelialization that has made necessary the longer periods of treatment.

Other Specific Therapeutic Measures.—There is as yet no experience that indicates whether the simultaneous administration of one of the sulfonamides with penicillin is of any value. This problem cannot be satisfactorily evaluated until more is known about the effect of penicillin therapy alone in the treatment of this disease. The same can be said for the use of artificial-fever therapy.

Regarding the use of anticoagulants such as heparin or dicumarol, sufficient evidence has accumulated to indicate that these agents do not enhance the action of penicillin and that the results obtained when these agents are used are no better than when penicillin alone is given. It is also well known that the use of these agents may be hazardous. It may be said, therefore, that anticoagulants have no further place in the treatment of subacute bacterial endocarditis.

Supportive Treatment.—Patients with subacute bacterial endocarditis, especially those seen late in the disease, present many of the features of chronic illness that require careful management. If the patient is having high fever, bed rest is advisable. In other cases the degree of activity allowed may be adjusted to the patient's strength. Patients who have lost weight should be provided with a nourishing diet, and in those with severe anemia blood transfusions may be indicated.

The use of digitalis and the restriction of the salt and fluid intake may be necessary in patients who show signs of a cardiac failure.

The careful management of convalescence in patients who recover from the infection is of the greatest importance. When treatment has been completed, even though the blood culture remains sterile and the vegetations may be assumed to have healed, the majority of patients still suffer from the residual effects of the chronic debilitating illness through which they have passed. In most instances several weeks, or more often several months, of convalescence are required before the patient has fully recovered his strength and energy. It is important, therefore, that his activities be regulated during the period of convalescence. If the situation is fully explained to the patient, needless discouragement at his failure to make more rapid progress can be prevented.

PRESENTATION OF CASES

In the space remaining we propose to present several cases that we have treated, which illustrate the principles that have been enumerated above and that also bring out some of the special problems encountered in the treatment of subacute bacterial endocarditis with penicillin. The first case selected is one of several that have shown rapid and progressive improvement under penicillin therapy

CASE I—K B., a 47 year old woman, had never had a recognized attack of acute rheumatic fever. At the age of 11 she was told that she had a heart murmur. She remained well, without any symptoms referable to the heart except for the occurrence of mild cardiac decompensation during the last trimester of her fourth pregnancy fifteen years before the present illness.

SUBACUTE BACTERIAL ENDOCARDITIS
STREPTOCOCCUS VIRIDANS

Fig 163 (Case I)—Clinical course of a patient with subacute bacterial endocarditis who responded promptly to treatment. The patient received 25 000 units of penicillin intramuscularly every three hours for twenty-one days. The total dosage was 4,200,000 units. The patient has been followed for one year and has remained well.

Sixteen weeks before admission to the Evans Memorial Hospital, without any known precipitating event, the patient developed generalized muscular aching and malaise. One week later she began to have afternoon fever often as high as 103 F., and severe night sweats. She was gradually forced to reduce her activity and for a month prior to admission she had remained in bed. The patient was not aware of any embolic phenomena. Two weeks before admission she entered another hospital, where the blood culture was found to be positive for *Streptococcus viridans*. She had lost 10 pounds during her illness.

On physical examination the patient appeared pale and chronically ill. There were no signs of cardiac decompensation. No petechiae could be seen in the skin or mucous membranes. There was marked clubbing of the fingers and toes. The

heart was slightly enlarged in the region of the left ventricle. The rhythm was regular. A grade 3 systolic murmur was present at the apex and was transmitted to the axilla. No diastolic murmurs were heard. The pulmonic second sound was accentuated. The spleen was palpable 2 cm below the left costal margin.

Laboratory studies revealed the hemoglobin to be 9.5 gm, the hematocrit 33 per cent, and the white-cell count 5850, with a normal differential count. The examination of the urine was negative. Two blood cultures were positive for *Streptococcus viridans*. This organism was tested for its sensitivity to penicillin and was found to be completely inhibited by 0.04 units of penicillin per cubic centimeter.

Course—The hospital course is shown in Figure 163. Treatment with penicillin was begun on the 5th day and was continued for 21 days. The dosage was 25,000 units, administered intramuscularly every three hours.

Twenty-four hours after the beginning of treatment the blood culture was negative, and it remained negative thereafter. Seventy-two hours after the beginning of treatment the patient felt much better and was aware of an increasing interest in her surroundings.

Despite the fact that a low-grade fever persisted, the symptomatic improvement was progressive. The day after treatment was completed the patient was allowed to sit up in a chair for a few minutes, and thereafter her activity was gradually increased, without ill effect. After treatment was discontinued, the rectal temperature did not go above 100° F, and except for one reading remained below this figure. No embolic phenomena were observed before, during, or after treatment.

The patient was discharged ten days after the completion of treatment. At this time she enjoyed a sense of well-being but still felt weak. Physical examination at discharge revealed no change in the clubbing of the fingers or in the heart murmur. The spleen was barely palpable and remained so for the first month after treatment. Two months after leaving the hospital the patient had regained her normal weight and was beginning to do light housework. By the fourth month the patient had fully recovered her strength and had resumed all her normal activities. During the last eight months she has felt entirely well. In this time the clubbing of the fingers has gradually receded and is now barely detectable. Frequent blood cultures have been taken during the year that has elapsed since treatment was completed. They have all been negative.

In summary, this patient had had known valvular heart disease for thirty-six years but had remained well, except for a brief episode of cardiac decompensation, until the onset of the symptoms of subacute bacterial endocarditis at the age of forty-seven. Treatment with penicillin was begun sixteen weeks after the development of the first symptoms. The total dosage of penicillin was 4,200,000 units, given over a period of twenty-one days. The blood culture became permanently negative twenty-four hours after treatment was begun, and the patient noted definite subjective improvement forty-eight hours later. A low-grade fever persisted until treatment was discontinued, and the spleen remained palpable until one month later. The patient had recovered her full strength and had returned to her normal activities four months after the completion of treatment. She has remained well for a period of one year.

Four of our other patients have shown a similar prompt response to the schedule of treatment followed in this case, and have remained

well now for periods varving from eight to sixteen months. While it is still too early to arrive at any final conclusions, the experience to date indicates that roughly half of the patients with subacute bacterial endocarditis caused by nonhemolytic streptococci respond to treatment in the same satisfactory fashion as did the patient that has just been presented. In the other roughly 50 per cent of cases the response is not so satisfactory and more difficulties are encountered. We shall devote the rest of this paper to discussing the cases that we have treated who have presented particular problems.

The next case is that of a patient who while apparently making a satisfactory response to penicillin therapy died suddenly on the ninth day of treatment.

CASE II—M. W., a 38 year old woman, had had a single attack of acute rheumatic fever at the age of 13. Following this attack she developed the signs of mitral stenosis, but had no symptoms of cardiac decompensation and remained well until the onset of the present illness.

Six weeks before admission, the patient began to lose her appetite and noticed increasing fatigability. There was no known antecedent illness or operation. The patient continued to work as a secretary until three weeks later when she became aware of feverishness in the afternoon and developed mild night sweats. These symptoms continued. Three days before entry a blood culture was obtained and was found to be positive for *Streptococcus viridans*. On the day before admission there was a sudden appearance of numbness and weakness of the fingers of the left hand. The patient had lost 10 pounds in weight during her illness.

On physical examination the patient appeared to be only slightly ill. The skin was moderately pale. One petechia was seen on the abdomen. Examination of the heart revealed slight enlargement in the region of the left ventricle and pulmonary conus. The rate was rapid the rhythm was regular except for occasional premature beats. Presystolic and systolic murmurs were heard at the apex. The pulmonic second sound was accentuated. There were no aortic murmurs. The lungs were normal. The liver and spleen could not be felt. There were no signs of cardiac decompensation. There was moderate weakness of the left hand and fingers. The deep tendon reflexes were hyperactive and equal. There were no pathologic reflexes. There was no clubbing of the fingers or toes.

Laboratory studies showed the hemoglobin to be 10 gm., the red cell count 3,400,000, and the white cell count 13,000, with 80 per cent polymorphonuclear leukocytes. Urinalysis was negative except for a few red blood cells in the centrifuged sediment. The nonprotein nitrogen was 28 mg. per 100 cc. Daily blood cultures during the first 4 hospital days were positive for *Streptococcus viridans*, the colony counts varying from 11 to 24 colonies per cubic centimeter. This organism when tested for its sensitivity to penicillin was found to be completely inhibited by 0.04 units per cubic centimeter.

Course—During the first four hospital days the temperature was continually elevated above 101° F., spiking to 103° or 104° each evening. On the fifth day treatment with penicillin was begun, 200,000 units being administered in each twenty-four hour period by means of a slow constant intravenous infusion. The total twenty-four hour volume of the infusion was 2000 cc.

Within twenty-four hours after the beginning of treatment the temperature became normal and it remained normal thereafter. A blood culture taken at this time was still positive but forty-eight hours after the beginning of treatment the

blood culture became negative Daily blood cultures thereafter showed no growth

Coincident with the fall in temperature the patient noticed progressive subjective improvement Her course continued to be extremely encouraging until the afternoon of the ninth day of treatment, when she suddenly complained of a severe headache and began to vomit Within an hour she became comatose, and four hours later respirations ceased A lumbar puncture performed two hours before death revealed a grossly bloody spinal fluid

The important postmortem findings were confined to the brain and heart. There was an extensive area of subarachnoid hemorrhage over the right hemisphere connecting with an area of softening in the right temporal lobe containing a fresh blood clot. The vessel responsible for the massive hemorrhage could not be identified

The heart weighed 420 gm The aortic, tricuspid and pulmonic valves were normal The leaflets of the mitral valve were fused, and the free edge of the valve was rolled and thickened Along the entire valve margin was an irregular row of soft, friable, grayish-red vegetations, each approximately 1 mm in diameter In one area on the auricular surface of the valve was an area measuring 2.0 by 1.2 cm that was completely covered with sessile vegetations Cultures of the vegetations were positive for *Streptococcus viridans*

In summary, this patient had been ill for only six weeks when treatment with penicillin was started Her general physical condition was fairly good, and the infecting organism was sensitive to penicillin The response to therapy was satisfactory, and she was making good progress when she suddenly died from a massive cerebral hemorrhage on the ninth day of treatment, presumably the result of a rupture of a mycotic aneurysm of the right middle cerebral artery or one of its branches

So far as could be determined either before or during treatment, there was every reason to expect that this patient would do as well as did the patient in Case I Unfortunately, her favorable course was interrupted by a fatal complication that was not amenable to chemotherapy One may of course reasonably speculate as to whether earlier treatment might not have prevented the development of this complication One may predict, however, that in a fair proportion of patients treatment will not be started until after complications similar to this one have developed Such cases are certain to limit the number of recoveries that can be effected by chemotherapy

Another important point illustrated by this case is that the failure to cultivate the organism from the circulating blood, even over a period of one week, did not mean that the vegetations had been sterilized

Just a week after this patient died, we had another experience that further demonstrated the fact that subacute bacterial endocarditis frequently presents complications that cannot be treated with chemotherapy A 30 year old man with subacute bacterial endocarditis caused by a nonhemolytic streptococcus that was sensitive to penicillin was admitted for treatment after he had had symptoms for eight months As in Case II there was a satisfactory immediate response to treatment, with a clearing of bacteria from the blood stream and a re-

turn of the temperature to normal within twenty-four hours. On the third day of treatment the patient suddenly developed acute cardiac failure with pulmonary edema. Treatment with digitalis and other measures resulted in temporary improvement, but the patient died in cardiac failure three days later.

Occasionally after apparently responding satisfactorily to a course of treatment, a patient suffers a relapse with a return of symptoms and positive blood cultures. Such relapses may occur at any time from a few days to several months after treatment has been completed. In such cases further therapy is indicated. It has usually appeared desirable with the second course of therapy to increase the daily dosage of penicillin and to give a more prolonged course of treatment.

The next case illustrates the successful response to a second course of treatment by a patient who relapsed after the first course. This case is also of interest because on the basis of the history, physical examination and laboratory studies it was impossible to detect any evidence of antecedent heart disease.

CASE III.—H. H., a 63 year old man, had never had any symptoms suggestive of acute rheumatic fever. He had seen his physician for minor complaints at frequent intervals over a period of many years, but no cardiac abnormalities had ever been detected. One month before the onset of the present illness a tooth had been extracted under local anesthesia. Four weeks later the patient became aware of a feeling of increased fatigability but continued with his work. After six weeks of feeling poorly he consulted his physician, who found his temperature to be 99.4° F but could detect no cause for the fever or symptoms. One week later there suddenly developed pain and an area of redness over the dorsum of the left foot. This gradually disappeared. Two weeks later another tender painful spot appeared in the palm of the right hand. The patient had mild chilly sensations at this time, but the temperature was never higher than 100.4° F and was usually less than 100° F.

During the next two months the patient continued to feel weak and tired but kept on with his work. Four months after the onset of the first symptoms a blood culture was obtained and was found to be positive for *Streptococcus viridans*. A second culture taken four days later was also positive, and the patient was admitted to a local hospital, where he received 12,500 units of penicillin (100,000 units a day) intramuscularly every three hours for fourteen days. Blood cultures taken every three days after treatment was begun were negative. The temperature remained below 99.4° F., and the patient noted a definite improvement in well-being. On the eighth day of treatment there was a small embolus in the left fourth toe. At the completion of treatment the patient was discharged. A blood culture taken two days later was negative.

One week after discharge the patient noted a return of malaise and low-grade fever. A blood culture taken two days later was positive for *Streptococcus viridans*. The patient was then admitted to the Evans Memorial Hospital for further treatment. He had lost no weight during this illness.

Physical examination was essentially negative. There were no petechiae in the skin or mucous membranes. The heart was not enlarged, the rhythm was regular, the sounds were of good quality and there were no murmurs. The spleen and liver could not be felt. There was no clubbing of the fingers or toes. The blood pressure was 145/80.

Laboratory studies showed the hemoglobin to be 14.2 gm., the hematocrit 43 per cent, and the white cell count 8900, with a normal differential count. Urinalysis was negative except for a few red blood cells in the centrifuged sediment. The nonprotein nitrogen was 31 mg per 100 cc. The blood Hinton test was negative. An electrocardiogram was normal. Fluoroscopic examination of the heart and a 7 foot roentgenogram of the chest revealed no abnormality of the heart or great vessels. A blood culture taken on admission was positive for *Streptococcus viridans*, with 8 colonies per cubic centimeter of blood. This organism was completely inhibited by 0.04 units of penicillin per cubic centimeter.

Course—The hospital course is shown in Figure 164. During the first 72 hours penicillin was administered by continuous intravenous infusion at the rate of 300,000 units a day. This method had to be abandoned at the end of that time

Fig 164 (Case III) —The second course of penicillin treatment in a patient who had relapsed one week after the completion of the first course. Following the second course he has remained well for ten months. This case was of considerable interest because there was no evidence of pre-existing valvular heart disease.

because of the development of a severe thrombophlebitis at the sites of the infusion. For the next twenty-five days penicillin was administered intramuscularly at the rate of 25,000 units every two hours. During the time that intramuscular therapy was given the patient was ambulatory.

The blood culture became negative twenty-four hours after the beginning of treatment and remained negative thereafter. After three days of treatment the patient noted a progressive increase in well-being.

On the day that treatment was completed the patient was discharged from the hospital. During the next two months he gradually recovered his strength completely and at the end of that time returned to full-time work. He has been seen at frequent intervals for the last ten months. Blood cultures have remained negative and there has been no return of symptoms. The examination of the heart is still entirely negative.

This patient's first course of therapy in the light of our present knowledge was obviously inadequate, and one could anticipate that in spite of the temporary improvement relapse would almost certainly occur. The apparently lasting improvement after the second more intensive course of penicillin therapy illustrates the desirability of repeating the treatment in patients who fail to respond to the first treatment, particularly if there is any reason to suspect that the therapy has been inadequate.

This case is also of interest in that it illustrates the mild, insidious course that subacute bacterial endocarditis occasionally pursues, and because so far as we have been able to determine the disease was engrafted on entirely normal heart valves.

The next case presents a slightly different problem from the preceding one. The blood culture became negative after treatment was begun but became positive again even while treatment was being continued.

CASE IV—D N., a 45 year old woman, had never to her knowledge had any of the symptoms of acute rheumatic fever. Two years prior to the onset of the present illness the signs of mitral stenosis were detected on routine physical examination. There had been no symptoms of cardiac decompensation. Ten months before the onset of symptoms a tooth was extracted under local anesthesia.

The patient was in good health until five weeks before admission, at which time she had a shaking chill, followed by a temperature of 103° F. For the next five weeks she had similar episodes of chills and fever at intervals of two to six days. In the intervening period she was afebrile and asymptomatic except for increasing weakness. One episode of fever was accompanied by the appearance of a painful red spot in a fingertip. During the present illness she had lost 20 pounds in weight.

Physical examination showed a middle aged woman who did not appear ill. Examination of the skin revealed 15 or 20 petechiae scattered over the body. The lungs were clear. The heart was enlarged to the left. The rhythm was regular. There was a faint crescendo presystolic murmur and a loud blowing systolic murmur at the apex. There were no aortic murmurs. The liver was palpable 2 cm. below the right costal margin and the spleen 3 cm. below the left costal margin. There were no signs of cardiac decompensation. There was no clubbing of the fingers or toes.

Laboratory studies showed the hemoglobin to be 11 gm., the red cell count 4,000,000 and the white cell count 10,400 with 89 per cent polymorphonuclear leukocytes. Urinalysis revealed a 1 plus albumin and a few red blood cells in the centrifuged sediment. The nonprotein nitrogen was 28 mg. per 100 cc. Five blood cultures taken during the first week were positive for *Streptococcus viridans*. A colony count performed on one occasion showed 68 colonies per cubic centimeter. This organism was tested for its sensitivity to penicillin and was found to be completely inhibited by 0.08 units per cubic centimeter.

Course—The hospital count is shown in Figure 165. Treatment with penicillin was begun on the sixth day with a dosage of 25,000 units intramuscularly every three hours. For the first three days after the beginning of treatment the blood culture was negative, but thereafter it again became positive and remained so until the nineteenth day of treatment, when the dosage was increased to 25,000 units every two hours. Again the blood cultures became negative for three days only to become positive once again. After fifteen days the method of administration was changed from intermittent intramuscular injections to a continuous

alysis revealed a 1 plus albumin and microscopic hematuria. The nonprotein nitrogen was 30 mg per 100 cc. During the first week in the hospital five blood cultures were obtained, three of which were positive for *Streptococcus viridans*. This organism was tested for its sensitivity to penicillin and was found to be completely inhibited by 0.02 units per cubic centimeter.

Course—When the first blood culture was reported to be positive, treatment with penicillin was begun. The subsequent course is set forth in Figure 166. It can be seen that during the 160 days in the hospital the patient received four courses of penicillin, separated from each other by only a few days.

With the first course of treatment, which consisted of the administration of 25,000 units of penicillin intramuscularly every three hours for twenty-one days, the patient showed definite improvement. The blood culture became negative after twenty-four hours, and the temperature returned to normal after seven days.

Fig 166 (Case V)—Clinical course of a patient who died of a cerebral embolus after receiving 45,000,000 units of penicillin during the course of 150 days. While the blood culture was never permanently sterilized, this patient's general condition showed very little deterioration during her long stay in the hospital.

Twelve hours after treatment was stopped the temperature rose to 102.4° F, and forty-eight hours later the blood culture again became positive. Treatment with penicillin was thereupon resumed, 25,000 units being given intramuscularly every two hours. When the patient showed signs of improvement, the dosage was reduced after ten days to 25,000 units every three hours. Within three days the temperature again became elevated, and five days later a continuous intramuscular infusion was begun at the rate of 200,000 units a day. At this time the spleen became palpable for a few days. It had not been felt previously and after about a week it could not be felt again.

When the patient failed to improve the daily dosage was increased to 300,000 units a day and was continued at this amount, first by constant intramuscular infusion and later by intermittent intramuscular injections, for thirty-seven days. At the end of this time the patient had been under continuous therapy for fifty-seven days.

Treatment was stopped for three days but was resumed as soon as the temperature began to rise. Three blood cultures taken during the time that treatment was omitted later proved to be positive.

The third course of penicillin consisted of a daily dosage of 500,000 units given in 12 divided doses at two hour intervals for fourteen days. The blood culture again became negative and the temperature returned to normal. During this course of treatment, however, showers of new petechiae appeared almost daily.

As soon as treatment was stopped, the blood culture became positive, although the temperature remained normal for two days. As soon as it rose, treatment was resumed. It was now thought that the patient would probably have to receive penicillin treatment continually for many months if any hope was to be held for eradicating the infection. Accordingly an effort was made to discover the minimal dosage that would keep the blood culture negative. As can be seen from the chart, the dosage was gradually increased from 50,000 units every twelve hours to 50,000 units every two hours before the blood culture was rendered sterile. After the blood culture had been negative for nine days the dosage was gradually reduced. Sulfamerazine therapy was begun at this time, with the hope that the combined use of the two drugs would permit the use of smaller doses of penicillin. When the dosage of penicillin was reduced however the blood cultures again became positive.

It might be stated at this point that despite the length of the illness the patient's general condition had remained extremely good. Except for the periods when the temperature was markedly elevated, she was comfortable and spent several hours each day sitting up in a chair and walking about the ward. During the latter part of the course, showers of new petechiae appeared almost daily, even at the times when the blood cultures were negative.

After sulfamerazine had been given for seventeen days, the patient complained of increasing nausea and it was decided to discontinue the drug temporarily. Five days later she suddenly complained of an excruciating headache, lapsed into coma, and died one and one-half hours later. An autopsy was not obtained.

This patient received a total of 45,000,000 units of penicillin in the course of 150 days. Despite this prolonged contact with penicillin, however, her organism showed no significant increase in its resistance to penicillin. The organism obtained in the last positive culture was inhibited by 0.04 units of penicillin, whereas the one recovered in the first blood culture was inhibited by 0.02 units. This difference in sensitivity is actually not greater than the range of error of the method of assay used.

In retrospect one may speculate as to whether the use of larger doses earlier in the course of the illness might have controlled the infection as it did in Case IV. Actually the latter patient came under treatment after the patient in Case V had died. This question, of course, cannot be answered. We can say, however, that there are cases on record of patients who have received several million units of penicillin a day over a period of weeks without eradication of the infection. In the light of our present knowledge, however, it seems reasonable to recommend that in those cases that do not respond to more moderate doses the daily amount of penicillin should be gradually increased, if possible, until a daily dosage is discovered that will keep the blood culture

sterile This dosage should then be continued for a minimum of three weeks

Actually, one of the greatest difficulties that the physician encounters in treating subacute bacterial endocarditis is in determining when the patient is making a satisfactory response to treatment Patients who become afebrile and whose blood cultures become negative a day or two after treatment is begun may relapse within a short time after it is completed Other patients whose subsequent course clearly indicates that the infection has been eradicated have not infrequently presented signs during treatment and for several weeks thereafter that strongly suggest an incomplete response to it Thus, experience has shown that fever, leukocytosis, splenomegaly, embolic phenomena, clubbed fingers and an elevated sedimentation rate persisting singly or together after the completion of treatment do not necessarily indicate that treatment has been unsuccessful

The last case that we shall present is an extreme example of this statement

CASE VI—F M., a 29 year old man, was discovered to have mitral stenosis at the age of 7 At 13 and again at 18 years of age he had attacks of acute rheumatic fever After recovering from the last attack, he had no symptoms referable to the heart and remained in good health until the onset of the present illness

Fourteen weeks before admission, without any known precipitating episode, the patient had a shaking chill without localizing signs He remained in bed for four days and then returned to work During the next eight weeks he noticed increasing fatigability and anorexia He continued with his usual activities, however, until five weeks before admission, when he had another shaking chill, followed by a temperature of 103° F The patient then took to bed, where he remained until admission During the intervening five weeks he had a daily afternoon temperature, often as high as 104.6° F, and frequent night sweats He rapidly became very weak and lost approximately 60 pounds in weight Two weeks before admission to the Evans Memorial Hospital he was admitted to a local hospital where a blood culture was found to be positive for *Streptococcus viridans* After treatment with sulfadiazine had effected no improvement the patient was transferred to this hospital

Physical examination showed a pale, emaciated young man, dripping with perspiration, mildly disoriented, and appearing acutely ill There were numerous petechiae in both conjunctival sacs but none in the skin The lungs were normal The heart was markedly enlarged in the region of the left ventricle and the pulmonary conus The rhythm was regular At the apex a crescendo presystolic murmur and a loud blowing systolic murmur were heard The spleen was palpable 2 cm below the left costal margin There was no clubbing of the fingers or toes

Laboratory studies showed the hemoglobin to be 8 gm the red cell count 3,000,000, and white cell count 7000, with 80 per cent polymorphonuclear leukocytes Urinalysis was negative except for a few red blood cells in the centrifuged sediment The nonprotein nitrogen was 40 mg per 100 cc Two blood cultures were positive for *Streptococcus viridans* with 200 and 300 colonies per cubic centimeter The organism was tested for its sensitivity to penicillin and was found to be completely inhibited by 0.04 units per cubic centimeter

Course—The hospital course is shown in Figure 167. On the day before treatment with penicillin was begun the patient suddenly complained of a severe headache and lapsed into a state of semicomatose. His neck was found to be markedly stiff and lumbar puncture revealed the spinal fluid to be grossly bloody.

Notwithstanding the patient's poor condition, treatment with penicillin was begun at the rate of 25,000 units intramuscularly every three hours. It was continued at this dosage for seventeen days. For the next four days 200,000 units were administered every twenty four hours by continuous intravenous infusion. Penicillin therapy was then discontinued.

The blood cultures became negative twenty four hours after treatment was begun and remained negative thereafter. The patient, however, showed no significant improvement aside from a slight lowering of the temperature. He remained semicomatose for the first ten days of treatment and was still stuporous and partly aphasic when treatment was completed. When questioned later, he had no recollection of ever having received penicillin.

Fig 167 (Case VI)—Clinical course of a patient who despite the persistence of fever splenomegaly embolic phenomena, and an elevated sedimentation rate for several weeks after the completion of treatment, progressed to an apparent complete recovery. Convalescence was extremely prolonged. The patient has now been followed for a period of fifteen months since the completion of treatment and has remained well.

From the chart it can be seen that the patient continued to have fever until seven and one half weeks after treatment was completed. During treatment no new petechiae or embolic episodes occurred, but on the ninth day after stopping treatment embolism of the right brachial artery occurred, and new petechiae appeared almost daily thereafter for the next six weeks.

Seventy five days after treatment was completed an enlarging pulsatile mass that was believed to be a mycotic aneurysm of the right common iliac artery was detected in the right lower quadrant of the abdomen. The aneurysm grew larger for ten days until it was the size of a small orange. Thereafter its size did not change.

It was not until six weeks after treatment was completed that we held any hope for recovery. From that time on, however, the patient showed slow but progressive improvement. Fifty days after treatment he was able to sit up in a chair but another thirty days elapsed before he was able to walk. At that time

he weighed 120 pounds, his normal weight being 175 pounds. Ninety-five days after beginning treatment the patient was discharged from the hospital. The spleen was still palpable at this time and remained so for another three weeks.

During the first three months after discharge from the hospital the patient gained rapidly in strength and his weight returned to normal. At the end of this time there was no longer an anemia and the white cell count and sedimentation rate were normal.

Six months after the completion of treatment the patient returned to work. Another nine months have now elapsed, during which time he has felt entirely well and repeated blood cultures have been negative.

This case demonstrates how difficult it may be at times to evaluate accurately a patient's response to treatment. All that can be said at the moment is that so long as the blood culture remains negative after treatment has been completed, the usual clinical signs that might be taken as evidence of continuing infection must be interpreted with caution. One cannot deny that such signs are disquieting, but the question as to when they should be taken as a signal for the resumption of therapy cannot be answered satisfactorily with our present limited experience. At the moment it is our practice not to give further treatment as long as the blood culture is negative, unless the patient's course as a whole appears to be definitely unfavorable.

CRITERIA FOR CURE

The question of what criteria can be established whereby one can be certain that a patient with subacute bacterial endocarditis has recovered from his infection must remain unanswered for the moment. The experience of others has shown that relapses may occur at any time within six to eight months after treatment has been completed, although they are commoner during the first month after treatment than after longer intervals. One case is known in which the patient, after being well for a year, developed anew the typical symptoms of the disease with positive blood cultures. It is of course impossible to say whether this patient actually relapsed or became reinfected.

At the present it is our belief that the prognosis in subacute bacterial endocarditis after treatment with penicillin should remain extremely guarded for the first three months. If the patient remains well during this period, the prognosis improves, but it seems unwise to consider that any patient is cured until at least a year has elapsed from the time treatment was finished. Increasing experience may well necessitate a revision of these figures. Furthermore, the likelihood of reinfection will probably always be present in these patients. With this possibility in mind, it will not be surprising in the years to come to see patients who have recovered from multiple attacks of subacute bacterial endocarditis.

PROPHYLAXIS

This discussion would not be complete if we did not close by urging that the prevention of subacute bacterial endocarditis is even more to

be sought than is its cure. The ideal goal in prophylaxis would of course be to prevent the development of rheumatic heart disease and congenital anomalies of the heart and great vessels. Since we do not possess at present the means of accomplishing this goal, we must direct our efforts, in so far as we can, to protecting the patient with rheumatic or congenital heart disease from the incidents or accidents that are known to precipitate subacute bacterial endocarditis.

Even here, our powers are limited. However, much may be accomplished if we can help these patients to avoid all unnecessary surgical operations, particularly those on the oral cavity. To this end early instruction in good dental hygiene is of primary importance. In addition these patients should be thoroughly and repeatedly instructed that should tooth extraction or tonsillectomy become absolutely necessary, they should insist on receiving before and after such procedures a potent chemotherapeutic agent as a prophylactic measure.

A suggested regimen for adults is to administer 2 gm. of sulfadiazine twenty-four hours before operation, and 1 gm. every four hours until forty-eight hours after. The usual precautions that are taken when patients are given a sulfonamide should, of course, be observed. Another regimen is to administer 50,000 or 100,000 units of penicillin intramuscularly no longer than a half hour before the projected operation, and 25,000 units intramuscularly every three hours for twenty-four to forty-eight hours after it. The two regimens may of course be combined.

Prophylactic chemotherapy of this type is now being widely practiced. It is far too early to determine its effectiveness, but until such a time as it is proved to be ineffective, its use appears to be fully justified.

There appear to be two possible mechanisms whereby such prophylactic chemotherapy may exert a beneficial effect. The first consists of a reduction in the number of bacteria at the site of the proposed operation as the result of the preoperative administration of a chemotherapeutic agent, with a resulting decrease in the possibility that organisms will be introduced into the blood stream at operation. By the second possible mechanism, the chemotherapeutic agent would prevent postoperatively the growth and multiplication of any bacteria that might gain access to the blood stream and become implanted on the heart valves. Since sterilization of the mouth is impossible, the second mechanism seems more likely to be operative if prophylactic chemotherapy is effective. It must be admitted, however, that preliminary studies have indicated that preoperative sulfonamide therapy results in a reduction in the incidence of bacteremia following tooth extraction.

Beyond the points outlined above it is not clear how much further one can at present proceed with the prophylaxis of subacute bacterial endocarditis. It has been suggested that all patients known to have valvular heart disease should receive chemotherapy with every res-

piratory infection Should a nontoxic chemotherapeutic agent that can be conveniently taken at home become available, such a program might well be worth adopting

SUMMARY

In this paper we have reviewed briefly the more important information that is known regarding nonhemolytic streptococcus subacute bacterial endocarditis The treatment of this disease with penicillin has been discussed and illustrative cases have been presented The following points may be repeated in summing up the discussion

1 The infecting organism must be susceptible to penicillin if a favorable response to treatment is to be expected

2 A daily dosage of 200,000 units is the minimal one that has been found to be effective Doses of 300,000 units a day may provide a greater margin of safety Only rarely are larger doses necessary

3 The duration of treatment should be at least two weeks and preferably three weeks In occasional cases more prolonged treatment is necessary

4 Intermittent intramuscular injection at two or three hour intervals is the most convenient and satisfactory method of administering penicillin

5 In 50 per cent of cases the infection responds promptly and apparently permanently to one course of treatment In the other 50 per cent, various complications may be expected These include death from causes not amenable to chemotherapy, failure to respond to the usual doses of penicillin, or the reappearance of symptoms and positive blood cultures either immediately after the completion of treatment or at a later date

6 If the blood culture remains sterile, the persistence of fever, splenomegaly, leukocytosis, embolic phenomena and an elevated sedimentation rate after the completion of treatment does not necessarily mean that therapy has been unsuccessful

7 The formulation of precise criteria for determining when a patient is cured of his infection cannot be made until more experience is available At present it appears advisable to wait until a patient has had negative blood cultures and has been free of symptoms for at least one year before considering him cured

8 Reinfection may occur at any time after the original infection has been eradicated It is not unlikely that multiple attacks of subacute bacterial endocarditis may be observed in the future.

9 The importance of the prophylaxis of subacute bacterial endocarditis has been reemphasized, and the practical measures that the physician can adopt have been outlined

THE MANAGEMENT OF CARDIAC EMERGENCIES

CAPTAIN JAMES M FAULKNER

MEDICAL CORPS, UNITED STATES NAVAL RESERVE

THIS discussion will concern itself with the treatment of the following conditions, which may present themselves as acute cardiac emergencies, requiring immediate measures for their relief

- I Cardiac Arrhythmias
 - 1 Paroxysmal Tachycardia
 - (a) Auricular
 - (b) Ventricular
 - 2 Auricular Flutter
 - 3 Auricular Fibrillation
 - 4 Adams-Stokes Syndrome
- II Cardiac Tamponade
- III Acute Left-sided Heart Failure
- IV Coronary Occlusion

CARDIAC ARRHYTHMIAS

Paroxysmal Auricular Tachycardia—Paroxysmal auricular tachycardia is characterized by the sudden onset of a very rapid and regular heart rhythm. The rate is usually between 160 and 220 beats per minute, but may be as low as 140 or even lower, and, in infants, is sometimes seen as high as 300. In the absence of heart disease it seldom leads to serious cardiac embarrassment, but in the presence of valvular or coronary disease it may precipitate either congestive failure or severe substernal distress, simulating that seen in coronary thrombosis. Ordinarily it gives rise only to faintness, giddiness, palpitation (often referred to as a fluttering feeling in the chest), and almost invariably to a compulsion to *lie down*. It is apt to be a recurrent condition and patients who have become familiar with it often hit upon tricks of their own which they have found effective in stopping attacks. Favorite devices are holding the breath, taking a long drink of water, and the Valsalva experiment (forced expiration with the glottis closed). I know of one patient who discovered that he could always stop an attack by standing on his head. Most patients agree that these maneuvers are more effective if they are applied at the very beginning of the attack than if they are withheld until the attack has been going on for some time.

The doctor who is called upon to halt a paroxysm of auricular paroxysmal tachycardia should bear in mind that his most effective

Nothing in this report is to be construed as official or reflecting the views of the Navy Department or the Naval Service at large

instrument is stimulation of the vagus, that extreme vagal stimulation will almost always stop an attack but at the expense of considerable discomfort to the patient, and that lesser degrees of vagal stimulation will often prove effective and should be tried first.

The simplest and best known maneuver is carotid sinus pressure. This is most effective if the patient is in the upright position or leaning slightly forward. Since stimulation of the right carotid sinus is more apt to be effective than the left, this is chosen first. The patient's head is rotated slightly to the left, the carotid artery is palpated anterior to the sternomastoid muscle and the carotid sinus is identified at the level of the angle of the mandible. The sinus is massaged with strong pressure against the cervical spine. If this is ineffective the same maneuver is carried out on the left, and if necessary both sinuses may be massaged simultaneously. It is well to wait about two minutes between each manipulation because for some reason as yet unexplained it not infrequently happens that the heart rhythm reverts to normal one or two minutes after stimulation has ceased.

The next procedure is to press on the eyeballs. This is less frequently effective than carotid sinus pressure, but sometimes works when the other fails. The amount of pressure applied will be determined by the pain threshold of the patient and the sang-froid of the doctor.

If these measures are unsuccessful, we must resort to more intense vagal stimulation. If the back of the patient's throat is tickled with a tongue depressor or if he sticks his own finger down his throat until he gags, retches or even vomits it will often bring about an immediate cessation of the attack. At this point the physician may well pause and consider whether any more drastic treatment is not likely to cause more discomfort to the patient than the arrhythmia itself. He will remember that these attacks are almost invariably self-limited and unless there is underlying heart disease which makes a continuation of the tachycardia hazardous he should temporize. The patient should be reassured, given a sedative (such as triple bromides 30 grains (2 gm.) or phenobarbital $1\frac{1}{2}$ grains (0.1 gm.) and put at rest in a quiet room. If, after several hours, the attack has not ceased spontaneously, he may be given syrup of ipecac in repeated doses (10 to 30 cc) until he vomits. This simple but unpleasant procedure will stop most attacks.

As a last resort acetyl-beta-methylcholine ("mecholy") may be given subcutaneously. This powerful vagal stimulant must be used with caution. The patient should be lying down in bed. A sterile syringe containing 1/60 grain (1 mg) of atropine sulfate should be at the bedside to be given subcutaneously or intravenously if an untoward reaction to the drug occurs. A bed pan should also be available in case the drug should cause an evacuation of the bowels. It is best not to use the drug in subjects with asthma as it will invariably provoke an attack in such patients. The dose is 15 to 30 mg in young individuals and 40 to 50 mg in persons over 50. It will cause marked

flushing of the face and body, sweating, lacrimation, palpitation and sometimes defecation. Nausea, vomiting or fainting are signs of clinical toxicity of the drug and call for counter measures. These are the application of a tourniquet above the site of the injection and the administration of atropine either subcutaneously or intravenously. The maximal therapeutic effect of the drug will occur one or two minutes after it is injected at the height of the flush. Its effect on the heart may be enhanced by massaging the site of the injection and by carotid sinus stimulation.

Paroxysmal Ventricular Tachycardia.—Unlike paroxysmal auricular tachycardia, paroxysmal ventricular tachycardia is usually associated with heart disease and it is not infrequently an alarming and serious complication of myocardial infarction. It is impossible to differentiate it from the auricular variety with certainty without the electrocardiogram, and treatment for it should never be undertaken without electrocardiographic confirmation. The rhythm is often slightly irregular so that it may give the impression on auscultation of rapid auricular fibrillation. It is not responsive to any of the methods of vagal stimulation outlined above.

As in paroxysmal auricular tachycardia it is well to lead off with a sedative such as triple bromides 30 grains (2 gm), pentobarbital $1\frac{1}{2}$ grains (0.1 gm) or morphine $\frac{1}{6}$ grain (10 mg). Quinidine is still the drug of choice in this condition and when given by mouth in the usual doses it is practically without danger, except in the presence of well marked delay in intraventricular conduction and in the very rare case of sensitivity to the drug. With these exceptions it is entirely safe to give quinidine sulfate by mouth in doses of 3 grains every hour up to 30 grains. If this dose is to be exceeded, however, as it not infrequently has to be to bring about the desired result, an electrocardiogram should be taken before each dose in order to stop the drug at the earliest appearance of a toxic effect, which will be a further spreading of the QRS complex. Under carefully controlled conditions 6 grains (0.4 gm) may be given every hour for ten doses with little hazard. If this dosage is ineffective it is better to abandon the oral route with all the uncertainties of assimilation and resort to parenteral administration. Quinidine may be given intravenously but is hazardous in doses above 6 grains (0.4 gm). For parenteral use it is safer to turn to quinine dihydrochloride which is marketed in $7\frac{1}{2}$ grain (0.5 gm) ampules. It is best given intramuscularly. If given intravenously it must be given very slowly—not faster than $\frac{3}{4}$ grain every two minutes. Even so it is not without risk and I have seen one death from ventricular fibrillation produced by it. The intramuscular injection which makes for slower absorption is less dangerous.

Auricular Flutter.—Auricular flutter resembles auricular paroxysmal tachycardia in that the rhythm is usually rapid and usually regular, but may be distinguished from it in many cases by the fact that the rate is

not so rapid (usually in the neighborhood of 140 beats per minute), and, furthermore, the rate may vary abruptly from time to time. Carotid sinus pressure will usually cause an abrupt but only transitory slowing.

Because the rate is not extremely rapid and because there is a tendency for it to revert to normal rhythm spontaneously it is not necessary to institute immediate measures for its relief unless it persists for several hours or unless the underlying cardiac condition makes it inadvisable to temporize. *Digitalis* is the drug of choice and may have one or more of three effects. It may slow the ventricular rate by increasing the grade of A-V block without breaking up the flutter of the auricles, it may convert the flutter into fibrillation and it may bring about reversion to normal rhythm. It most frequently does all three things in succession. Any of the standard U.S.P. *digitalis* preparations in full digitalizing doses (15 to 22½ grains [1 to 1.5 gm.] of the dried leaf in twenty-four hours), will be found useful but in my experience lanatocid-C has been particularly satisfactory when prompt action is desired. It should be given in doses of 0.8 mg intravenously and repeated in four hours if necessary.

Auricular Fibrillation.—Auricular fibrillation is much more commonly encountered than auricular flutter. While usually associated with heart disease it is not infrequently observed as a complication of surgical operations or acute infections in older people without other evidence of heart disease and is particularly common in hyperthyroidism. From the point of view of emergency management the features which may call for immediate relief are distressing palpitation and tachycardia. The subjective distress is usually dependent on the tachycardia and patients experience considerable if not complete relief from the palpitation when the rate is brought down to normal limits even though the abnormal rhythm persists. *The immediate objective of treatment is to restore the heart rate to normal rather than to restore normal rhythm* and this is best accomplished by quick digitalization as outlined under the treatment of auricular flutter. Quinidine is not advocated as an emergency treatment in auricular fibrillation but should be reserved for those cases which do not revert to normal rhythm spontaneously following preliminary digitalization.

Adams-Stokes Syndrome.—Adams-Stokes syndrome is sudden loss of consciousness due to temporary standstill of the heart. It is seen in high grade partial heart block and in complete heart block and is particularly apt to occur when complete block is not established and there is oscillation between an auricular and a ventricular pacemaker. In the transition from partial to complete block, when auricular impulses no longer reach the ventricle, the ventricular pacemaker may be slow in taking up the rhythm with a resulting excessively long diastolic pause. When such a pause exceeds about eight seconds, sudden loss of consciousness takes place and the aim of therapy is to

stimulate the ventricular pacemaker to a fast enough inherent rhythm so that intervals between beats will never exceed this critical period

The aspect of Adams-Stokes syndrome which the physician is usually called upon to treat, as an emergency measure, is the case in which the patient is having a series of attacks, going in and out of a state of unconsciousness perhaps with convulsions. Under these circumstances the drug of choice is epinephrine (0.5 cc) subcutaneously. This will almost invariably abolish the attacks temporarily (at least for an hour or two) when the dose may be repeated. If a more lasting effect is desired epinephrine in oil (1 cc intramuscularly) may be given two or three times in twenty-four hours. If continued treatment is necessary ephedrine $\frac{3}{8}$ grain (22 mg) or paredrine $\frac{1}{2}$ to 1 grain (30 to 60 mg) every four to six hours by mouth may prove adequate.

It is seldom that the physician will be called upon to treat an individual attack since they are necessarily either very brief or fatal, but if he is faced with this problem he must act quickly. The first thing to do is to strike the chest over the cardiac apex sharply with the knuckles several times. This may mechanically stimulate the heart to contract. If this does not bring about resumption of rhythmic contractions epinephrine (0.25 cc of 1:1000 solution) should be immediately injected into the heart. If epinephrine is not at hand the simple thrusting of a needle into the heart may provoke contractions. Needless to say, no time can be taken for sterile precautions. Because these maneuvers are familiar to all of us and because we have seen them carried out with almost invariable lack of success in patients in the death throes of other diseases we should not scorn to use them here, for this is one situation in which they are definitely indicated.

CARDIAC TAMPONADE

Cardiac tamponade is the condition in which excessive fluid in the pericardial cavity exerts pressure on the great veins and thus interferes with venous inflow to the heart. It may be caused by inflammatory exudates such as in tuberculosis, pneumococcal or rheumatic pericarditis or by hemorrhage from rupture of an aortic aneurysm or of the heart itself. Less commonly metastatic new growth involving the pericardium gives rise to excessive outpouring of fluid into the pericardial cavity. Most dramatic of all are those cases which are due to hemorrhage into the pericardium from stab or bullet wounds of the heart. Since the pericardium is a relatively inelastic membrane, when it is filled with fluid a point is reached where any further increase in its contents causes an encroachment on the caliber of the great veins which enter it. This leads to engorgement of the veins of the neck, enlargement of the liver and a decrease in the stroke volume of the heart which is reflected in a drop in the systolic blood pressure and the pulse pressure.

The immediate therapeutic problem is to lower the intrapericardial

pressure when this has reached a critical point. The best guide as to when to interfere is the pulse pressure. When this falls below 20 mm of mercury the pericardium should be tapped and the fluid removed. This is done with the same technic and apparatus as one would use for a thoracentesis using a short beveled needle to minimize trauma to the heart. The recommended site for tapping is in the fifth left intercostal space about 2 cm inside the left border of percussion dullness. If fluid is not obtained the needle should be reinserted closer to the sternum or in the fourth intercostal space. Another approach is through the epigastrium, the needle being inserted in the angle between the left costal margin and the ensiform and directed upward, inward and to the left in the direction of the left scapula. All removable fluid should be taken away. Immediate improvement in the patient's condition will be noted after the removal of 200 or 300 cc.

In small wounds of the heart, removal of blood from the pericardium by tapping may be all that is necessary. I have seen three such cases—one from a knife wound and two from small shell fragments in which the hemorrhage stopped spontaneously and recovery took place without resort to open operation and suture. Such cases must be watched with greatest care after the first tap to detect signs of recurrence of tamponade which indicate continued bleeding. If signs of pericardial fluid persist but without tamponade it is best to wait and allow it to absorb. If tamponade returns quickly, indicating continued brisk hemorrhage, immediate open operation and suture of the wound should be attempted. If there is a gradual recurrence of the signs of tamponade over a period of hours suggesting a slow oozing of blood into the pericardium, tapping may be again resorted to.

In cardiac tamponade due to hemorrhage, intravenous plasma or whole blood is of particular value because it helps to raise the venous pressure and thus directly to increase the cardiac output. The fact that the venous pressure is already elevated is not a contraindication to raising it still higher by transfusion, because its direct effect is to increase the venous inflow into the heart.

ACUTE LEFT SIDED HEART FAILURE

Acute pulmonary edema of cardiac origin results from an overloading of the pulmonary circuit due to failure of the left ventricle to expel as much blood as the right ventricle feeds into the lesser circulation. Because of the limited space allowable for the accommodation of surplus blood in the lungs a discrepancy of only a drop per beat in the output of the two ventricles will inevitably lead in the course of a few hours to extreme engorgement of the pulmonary blood vessels and edema. The most common causes are failing hypertensive hearts, aortic insufficiency or stenosis, infarction of the left ventricle and a tight mitral stenosis. Except in cases of recent infarction the onset of acute pulmonary edema can usually be traced to unusual

exertion, excitement or infection. It is manifested by dyspnea at rest, orthopnea, cough, which may be dry at first but in later stages is productive of white or pink frothy sputum, and cyanosis, which may be marked. The blood pressure is characteristically unchanged or raised. Venous engorgement may or may not be evident.

The object of treatment is to shunt some blood away from the right heart temporarily. This may be accomplished simply by venesection of 300 to 600 cc. If the situation appears to call for quick action only a knife and basin are absolutely required for the blood letting. Relief is usually prompt and dramatic. Often patients who appeared to be at death's door will, within a few minutes, declare they feel as well as ever. Other, less drastic methods are, however, often effective and may be tried while preparations are being made for the venesection if it proves necessary. These are (1) the administration of nitroglycerin grain 1/100 (0.5 mg) under the tongue which has the effect of pooling blood in the splanchnic circuit and thus reducing the return flow of blood to the heart, or (2) the application of tourniquets to all four extremities with a pressure sufficient to prevent venous return flow from these parts. A considerable amount of blood can be excluded from the circulation in this way. The best tourniquet for this purpose is the blood pressure cuff inflated to about 50 mm of mercury. The tourniquets should be left on for about half an hour and released one at a time at intervals of a few minutes. It is a technic which in my experience has been satisfactory in the hospital where plenty of assistance and apparatus is available, but which is sometimes difficult to apply in the home. Whatever the technic used, a hypodermic injection of morphine sulfate $\frac{1}{4}$ grain (15 mg) should be given at the onset of the attack. This in itself appears to have a specific effect over and above what one would expect from merely alleviating the sense of dread and anxiety which are almost invariably associated with it.

CORONARY OCCLUSION

The intimate relationship between angina pectoris and coronary thrombosis is now well recognized and, indeed, there is evidence from postmortem studies of the coronary circulation that angina pectoris is practically always associated with thrombosis of one or both of the main coronary arteries. From the practical point of view it is justifiable to *treat the first attack of angina pectoris as if it indicated a recent coronary thrombosis. The same doctrine applies to any abrupt decrease from the usual amount of exertion required to bring on an attack* (provided extraneous factors such as anemia, infection, hyperthyroidism and exposure to cold are ruled out), *and especially to the onset of angina decubitus.* If we recognize such attacks as danger signals quite different in their significance from the oft-repeated attacks of angina of effort we may, by appropriate measures, lessen the likelihood of myocardial infarction. Acting on the assumption that such attacks may

mean that an actual coronary thrombosis has occurred we should do everything possible to rest the heart until a collateral circulation has had time to establish itself

Once we assume that coronary thrombosis has taken place the immediate objective of treatment is to prevent the onset of myocardial infarction or at least to keep the size of the infarct as small as possible. Infarction results when the local demand for oxygen exceeds the available supply. The aim of treatment therefore is first to reduce the demand for oxygen by complete rest while collateral channels are accommodating themselves to feed the area formerly supplied by the occluded vessel and, second, to increase the local arterial oxygen supply if this be possible.

Objective No 1, complete rest, is obtained by putting the patient to bed at once. The bed should have a moderately high head rest. He should be given morphine $\frac{1}{4}$ grain (15 mg) at once and this should be repeated if pain continues. This will not only relieve the physical pain but will alleviate to some extent the dreadful anxiety which is so often associated with this condition.

Objective No 2, augmentation of the local oxygen supply to the affected myocardium, is to be attempted by increasing the oxygen content of the arterial blood. This is most effectively accomplished by the administration of 100 per cent oxygen in a closed mask. Even though cyanosis is not evident and the oxygen saturation of the arterial blood is normal the additional oxygen which this makes available both as oxyhemoglobin and in physical solution in the blood may be of critical value in combating the local myocardial anoxia. As an indication of this effect one not infrequently observes complete relief of heart pain on administration of oxygen with recurrence when the oxygen is discontinued. In general, the oxygen should be continued as long as heart pain persists.

Complete rest, morphine and oxygen are the mainstays of immediate treatment in coronary thrombosis. Nitroglycerin is not indicated and may actually be dangerous in cases with impending circulatory collapse. Aminophylline 4 grains (0.25 gm) intravenously may be used as an adjunct for the relief of pain but it cannot take the place of morphine. Papaverine has not yet convincingly demonstrated its usefulness in coronary occlusion as it has in peripheral arterial occlusions and further clinical trial will be necessary to establish its efficacy as a coronary vasodilator in this condition.

A brief outline has been given of emergency measures for the relief of the common acute cardiac disorders. It will be noted that these measures are highly specific and depend upon equally specific accuracy in diagnosis for their successful application.

THE THERAPEUTIC CONTROL OF RECURRENT PEPTIC ULCER

FRANZ J INGELFINGER, M D * AND ROBERT E MOSS, M D †

THE patient with an uncomplicated peptic ulcer presents a rather startling therapeutic paradox. His immediate response to medical therapy is excellent, his outlook for the future, by contrast, is dark. The chances are more than fifty-fifty that his ulcer will again trouble him within two years, and the likelihood of a recurrence in five years is probably over 65 per cent ^{1, 2, 3}. It follows that emphasis today need not be placed on the immediate therapy of the active ulcer, for which several satisfactory regimens have appeared in these pages, ^{4, 5, 6, 7} but upon the ways and means whereby reactivation of a healed ulcer can be prevented. Recent studies with enterogastrone, ⁸ a gastro-inhibitory substance extracted from the small intestine, hold out the hope that such substances may eventually be used for the long-term therapy of the ulcer patient. Enterogastrone, however, is still in the experimental stage, and at present one must content himself with more indirect methods of combating ulcer recurrences.

The methods outlined in this clinic are directed against those factors which are generally believed to play a part in the pathogenesis of a peptic ulcer. Both physician and patient may argue that some of the procedures are unnecessary, time-consuming and expensive, particularly since the patient under discussion has a healed ulcer and is free of symptoms. In view of the high incidence of recurrences, however, such arguments cannot bear much weight. In the long run, time and money lost in taking care of a recurrent ulcer—possibly an ulcer complicated by bleeding or obstruction,—greatly exceed the loss incurred by adopting a program aimed at preventing the recurrence. Too vigorous a program, it is true, will be discouraging and will lead to deviations from the too narrow path. The best schedule calls for some effort on the part of the patient, but not for a wholesale abandonment of the pleasures of life.

From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston.

*Assistant Professor of Medicine, Boston University School of Medicine, Member of Department, Robert Dawson Evans Memorial, Physician, Medical Service, and Chief, Gastrointestinal Outpatient Clinic, Massachusetts Memorial Hospitals.

†Instructor in Medicine, Boston University School of Medicine, Assistant Physician, Robert Dawson Evans Memorial, Assistant Visiting Physician and Chief, Psychosomatic Medicine Outpatient Clinic, Massachusetts Memorial Hospitals.

How successful is a program of prevention apt to be? Obviously, no guarantee can be given, some ulcers will recur no matter how carefully the patient is handled. On the other hand, we believe that the methods here outlined will, in a large number of ulcer cases, reduce the chances, frequency and severity of recurrences.

A SUGGESTED REGIMEN

The patient is assumed to have had a peptic ulcer, now healed and not causing any symptoms. Some parts of the regimen to be prescribed—i.e., those dealing with the patient's education and personality—should actually be started during treatment for the active ulcer.

1 *Education*.—The basic facts of peptic ulcer should be explained to the patient. By giving him an appreciation of the causes and course of his illness, two objectives will be attained. First, he will not be subject either to the carelessness of ignorance, or to the worry occasioned by various misconceptions that he may harbor. Second, he will follow directions more intelligently and more cooperatively if he understands the purpose of the prescribed regimen. The exact terminology used by the physician in elucidating peptic ulcer naturally depends upon the patient's background, but the following major points can be expressed in language understandable to most laymen.

(a) The exact cause of peptic ulcer is unknown, but physicians do know that an ulcer gets worse when the stomach is overly active and produces more than the usual quantities of acid.

(b) Excess activity and excess acid production by the stomach are particularly apt to occur under the influence of certain mental states and as a result of poor dietary habits. Therefore, the aim of ulcer prevention is adjustment of the mental states and elimination of poor habits. In addition, gastric acidity can be diluted and partially neutralized by the frequent intake of suitable foods and, if needed, medicines.

(c) Individual peptic ulcers can be cured quite readily, but the *tendency* of the patient to get an ulcer cannot be cured. ulcers can and do reappear under the proper conditions. Hence, if the patient is to avoid a recurrence, he must be ready to follow a moderate form of treatment for years.

For purposes of reassurance, the patient is told that duodenal ulcers never become cancerous. Whether he should be warned of complications—i.e., perforation, bleeding and obstruction—is a debatable point. To mention these dangers in a blunt or threatening fashion will serve no purpose but to make the patient unduly apprehensive. On the other hand, he should be informed of the possibility of bleeding so that he may acquire the habit of observing his stools routinely for signs of melena or blood.

2 *Psychotherapy*.—That peptic ulcer patients present striking similarities in appearance and in personality is generally recognized. Most

therapeutic regimens, consequently, advocate treating the individual as well as the ulcer. How can this be done? Simple admonitions to "take things easily" and to "stop worrying" are not sufficient, the patient obviously would rest and free himself of worry if he could. On the other hand, it is neither necessary nor practical to refer most ulcer patients to a trained psychiatrist. Much can be accomplished by the physician who grasps the essentials of the ulcer patient's personality and who is willing to practice some of the simpler techniques of psychotherapy.

Description of the Personality—Freudian psychoanalysis⁹ indicates that the ulcer patient has a strong wish to be cared for and loved as he was in infancy. As a result of the early infantile association of being loved with being fed, he desires food as a symbol of security and affection, a desire which maintains the stomach in a constantly active state. Such an attitude is incompatible with the striving of the adult for independence and activity. Hence, the wish to be cared for and fed is repressed into the unconscious, while the conscious mind is occupied in overcompensatory fashion with desires to be the efficient, responsible, conscientious, aggressive leader. As a result, marked conflict is present within the individual and is evidenced by chronic emotional tension.

Approaching the problem on the conscious level by the interview method, Draper and his associates¹⁰ have reached similar conclusions which they express somewhat differently. Ulcer patients, according to these authors, are extremely conscientious victims of chronic fear, who are driven to strive constantly toward some goal regardless of the difficulties encountered. Their driving fear stems from their dimly sensed awareness of the "feminine component" (passive, receptive tendencies) in their make-up which seems to threaten their ability to play successfully the masculine role in life. Thus "basic male fear" presses them to reassure themselves by overemphasizing their virile, aggressive tendencies.

Thus, the male ulcer patient suffers from a deep-seated conflict which is manifested in an excessive load of anxiety—apprehensive anticipation—and concomitant bodily tension. Plainly he must be restlessly active, worrisome and unable to relax. A similar emotional pattern usually characterizes the female ulcer patient, although the underlying conflicts are influenced by the difference in sex.

Correlation of Gastric Physiology and Personality Reactions—Suggestive observations of far-reaching importance have been made by Wolf and Wolff¹¹ on the stomach of their subject, Tom, through whose gastrostomy they were able to study the physiologic changes in gastric function occasioned by varied stimuli. In response to acute aggressive feelings and anxiety, his gastric mucosa became engorged and much redder than usual, the levels of free acid secretion and total volume of gastric juice were three times normal, and there was a

vigorous increase in gastric motor activity. Similar changes of hyperemia, hypersecretion, hyperacidity and hypermotility occurred and persisted during periods of prolonged anxiety and resentment, nor did these effects subside during sleep. Tom's emotional reactions, in short, caused his stomach to assume a state of preparedness for the reception and digestion of food.

Further, in normal subjects and in patients with the clinical diagnosis of peptic ulcer, gastritis and duodenitis, Mittelman and Wolff¹² showed that hypermotility, hypersecretion and hyperacidity occurred in a setting of anxiety and resentment. Such functional disturbances persisted throughout the duration of these emotions and did not abate during sleep. While these changes were present, subjective complaints of pain and epigastric burning were likewise present. The difference between the reactions of the normal subjects and those of the patients was simply a matter of degree.

These observations point toward the local mechanisms for translating emotional reactions into gastroduodenal functional disorders which presumably lead to symptoms and structural changes. They also point the way toward effective management of the patient.

Psychotherapeutic Method—Much, then, must be known about the patient in order to understand what influences are affecting his stomach. He should, accordingly, be interviewed privately, in a leisurely, friendly manner that will convey to him the impression that one is interested in him as a person. To encourage him to talk freely about himself, he is asked to describe the onset and course of his symptoms in detail, as these are generally uppermost in his mind. By simple questioning, he can be led to elaborate upon the setting—environmental and subjective, in which symptoms first appeared, persisted or recurred. It is important to ask him how he felt at these times, what he thought about, how he got along with others, how well he was succeeding in his work, and how he viewed his future.

EXAMPLE 1—The value of probing closely into the setting in which a symptom first occurs is exemplified by a patient convalescing from a subtotal gastrectomy for obstructing duodenal ulcer. The patient reported that he had begun to vomit as soon as he got home from the hospital and had vomited frequently especially after taking orange juice, during the succeeding three weeks. When asked what the orange juice had reminded him of, he recalled that it had upset him repeatedly prior to operation and that he had suddenly thought of this while drinking it. Further inquiry revealed that vomiting had actually begun two days prior to discharge, shortly after he had taken orange juice at breakfast. All the previous night, he remembered, he had felt "jittery" and had slept poorly because he had been given an intravenous injection (a liver function test) the afternoon before. This injection had been given with little explanation; he had immediately concluded that something was still wrong with him and had become acutely anxious. He had thought he could taste the material injected and that it tasted like vomitus. Against this background, the orange juice, which he had been taking daily without distress, precipitated his vomiting. Following discharge, he could not lose the fear that something was amiss, and the gastrointestinal tension was perpetuated, relieved somewhat by periodic vomiting. The elic-

ing of this chain of events opened the way to simple explanation of the purpose of the injection, and to reassurance as to the good result obtained by his operation. Thereafter, the patient ceased to be troubled by vomiting and was able to drink orange juice with impunity.

Usually, an outline of the habitual emotional patterns of the patient during the period of his illness can be obtained at the first interview. This outline suffices for the preliminary formulation of the patient's problem in terms that he can understand. One shows him by summarizing the evidence he has presented that he has an underlying sense of insecurity which is conscious to him as anxiety. This anxiety forces him into a state of constant preparedness for action, manifested by general bodily tension and an inability to relax. The patient usually means these things when he says that he always worries. Experience indicates that any eagerness on the part of the physician to give a more penetrating interpretation early in therapy is unwise. The patient will seldom accept anything more than a rough sketch of the problem, and may well be driven away by an attempt to give him deeper insight quickly.

However, expanding the formulation by pointing out that the patient resembles in his personality make-up a great multitude of peptic ulcer bearers adds to its force and appears to give him a sense of relief by showing him that he has many fellow-sufferers. He is then more easily convinced that his type of personality can lead to overactivity of the stomach. He shows much interest in gaining a clearer picture of the mechanism that produces his symptoms and is, consequently, receptive to instructions aimed at giving him relief.

EXAMPLE 2—The beneficial effect upon acute symptoms of the above approach is well exemplified in the case of a 44-year old white man whose ulcer symptoms dated back twenty years. He had been admitted to the hospital because of symptoms indicating severe pyloric obstruction. Constant aspiration of stomach contents for three days, followed by a strict feeding regimen and nightly aspiration, resulted in little relief of pain. The patient was interviewed on the seventh day and the relationship between his anxious, aggressive attitude and his ulcer symptoms was pointed out. He was then given a brief description of the effects of this attitude upon his stomach. The impression this made upon him was striking; he concluded that he could "let go" of much of his anxiety, at least temporarily, and that his aggressiveness was really hurting only himself. Thereafter, his symptoms were greatly alleviated, despite the later finding at operation that the obstruction was largely due to scar tissue.

At the end of the first visit, the procedure to be followed subsequently is outlined to the patient. He will be seen weekly, preferably for one hour at each visit, during which he will be asked to talk in greater detail and with complete frankness about himself. Chronological order is not essential, as significant relationships will come out eventually no matter where he starts. Questions may frequently be necessary, at first, to keep him going, or to bring out further details. As the story of his significant interpersonal relationship unfolds, he is

given a summarizing interpretation at the end of each interview. His appreciation of the reasons behind his early and persisting insecurity will gradually deepen, and he will realize how this feeling of insecurity determined his emotional reactions and, hence, his behavior and health throughout his life.

The development of insight, in this fashion, generally relieves a patient of much of his anxiety with concomitant lessening of his gastric overactivity. The patient, however, must be helped to apply his new knowledge and to understand his reactions in varied situations coming up in his daily living. It is this "working-through" of his problem in as many ramifications as possible that gradually effects a lasting change in attitude which can be summed up as growth in emotional maturity.

In addition, he may be started on a program designed to train him in the art of bodily relaxation. For the intelligent patient a satisfactory recommendation is that he obtain a copy of *You Must Relax* by Jacobson¹² and start putting its principles into practice. Much simplified adaptations of these principles may be presented to the patient who seems unlikely to benefit from reading the book.

The physician, finally, emphasizes that peptic ulceration is the end result of a long chain of circumstances involving the patient's total personality, that successful treatment requires reeducation of his emotional responses as well as a medical regimen, that there is no shortcut to the desired result, and that the length of time necessary to effect readjustments in his personality will be dependent upon his cooperation.

3 Diet—A fairly liberal diet can be offered to the patient with a healed ulcer (Table 1). Much more important than the type of food, however, is *regularity* of eating habits. The patient must eat at the same times every day. This rule has to be stressed particularly to traveling salesmen and others whose work is apt to interfere with regular eating habits. Actually, there are very few occupations which cannot be harmonized with regular food ingestion.

Interval feedings of milk must be taken regularly in the middle of the forenoon, in the middle of the afternoon, and at bedtime. If the interval between the evening meal and bedtime is long, an additional glass of milk in the middle of the evening is advisable. Except when asleep, the patient should never go more than three hours without taking food or drink. Milk is without doubt the substance most suitable for interval feedings, but compromises may be made with the patient's taste by using flavoring egg-nogs, custards, junkets, or vegetable purées made with milk. With the milk, plain crackers or cake may be taken if the patient so desires. On the other hand, the patient must understand that other foodstuffs—particularly coffee and soft drinks—are not acceptable substitutes for milk.

Certain foods present particular problems. Caffeine-containing beverages are known to stimulate gastric secretions,¹⁴ hence allowing a

cup of coffee at breakfast (Table 1) may seem questionable. Usually, however, an adequate amount of other food taken in the morning will dilute and partially neutralize whatever extra acid is secreted in response to the coffee. The same arguments apply to citrus fruits and their juices. The practice of diluting orange juice half-and-half with

TABLE 1 —DIET FOR THE PATIENT WITH A HEALED PEPTIC ULCER

Soups Pureed vegetable soups, preferably diluted with milk. Chicken or meat broths, either clear or with rice. Clam or fish chowder made with milk and potatoes (no onions).

Meats As desired, except spiced or pickled meats, very tough meats, or sausages.
Fowl As desired.

Fish As desired except spiced, kippered or fried fish. Avoid sardines.

Shellfish As desired except crab meat.

Potatoes, Rice, Noodles, Macaroni, Spaghetti As desired. For sauces, plain tomato sauce made from canned tomato soup and grated cheese may be used.

Bread Finely milled bread, whether wheat or rye. Avoid bread containing coal material or seeds of any type. Griddle cakes may be used. Plain crackers made of well-milled flour.

Vegetables Avoid raw vegetables. Peas, string beans, squash, asparagus, carrots, beets, spinach, lima beans, tender cauliflower may be used as they are ordinarily cooked. Any other vegetable should be puréed, or strained if it contains seeds.

Eggs As desired.

Cheese Cream, cottage, muenster, Swiss, mild (white) American. Avoid cheese spreads.

Butter, Oleomargarine As desired.

Sugar, Jelly, Honey, Maple Syrup As desired.

Milk, Cream, Cocoa As desired (flavoring may be added).

Cereals Any cooked cereal not containing bran. Corn flakes, puffed rice, whole flakes, dry oatmeal products.

Fruit Apple sauce, ripe banana, baked apple (avoid skin), stewed prunes, canned pears and peaches as desired. Orange, tomato, grape, or prune juice, grapefruit or orange halves, sliced peaches may be used if taken on the full stomach immediately after a meal.

Coffee or Tea One cup of either may be allowed *with* breakfast.

Desserts Fruit as above, junket, jello, custard, ice cream, rice or cornstarch puddings (no raisins), fruit whips, gelatine products, plain cakes and cookies (no nuts).

Avoid the following

All spices, catsup, mustard, "hot" sauces, relishes, pickles, spicy dressing or stuffing.

Alcohol

Nuts

Carbonated beverages

hot water has little to recommend it, for the only positive effect of this procedure is partial destruction of the heat-labile vitamin C contained in the juice. If the patient experiences heartburn or any other gastrointestinal symptoms after breakfast, it is probably wise to omit both coffee and citrus fruits.

Some patients make a practice of "testing" prohibited foods, to

they eat, let us say, sausage and sauerkraut, experience no ill effects, and understandably reach the conclusion that they need no longer deprive themselves of the pleasures of sausage and sauerkraut. The patient must be cautioned against such "testing." He must realize that when his ulcer is healed, he can probably get away for the moment with eating anything but that repeated ingestion of undesirable foods may contribute to an eventual ulcer recurrence.

Vitamins are adequately supplied by the diet. If the patient is unable to tolerate citrus fruits, he requires a daily supplement of 75 mg of ascorbic acid.

Alcohol presents a problem in the treatment of ulcer. It is undoubtedly a stimulant of gastric secretion. On the other hand, some feel that its relaxing effects on the mind more than offset its damaging effects in the stomach. It is our belief that relaxation can be achieved more beneficially by other and safer means, and that ulcer patients should entirely abstain from alcoholic drinks.

4 *Smoking*—Over one hundred years ago, Cruveilhier¹⁵ observed that ulcer patients become so irritated at their dietary restrictions, that "there even arrives a period when such stimulants as game succeed much better than white meats." An analogous situation obtains with respect to smoking. Those ulcer patients who can stop smoking without too much effort should certainly do so. But if the attempt to give up smoking leads to an intolerable increase in tension, the denial of tobacco may do the individual's gastrointestinal tract more harm than good. As a compromise, he is allowed to smoke when his stomach is full (i.e., when the presence of food may counteract any noxious effect that smoking may exert), but never when his stomach is empty. This advice runs counter to some very positive statements in the literature,^{5, 16} but not all are agreed on the detrimental effects of smoking in the ulcer patient.¹⁷

5 *Medications*.—Except as indicated under *Preparedness*, no medications are indicated.

6 *Exercise*—Physical exercise, whether during the pursuit of his occupation or at sports, does not harm the patient with a healed ulcer. As is true of all his activities, however, physical *fatigue* or strenuous activity to which the patient is not accustomed are to be avoided.

7 *Follow-up*.—After the emotional problems have been satisfactorily worked out, the patient should be seen once every three months to obtain information not only of his progress, but also concerning his adherence to the prescribed regimen. Often a little reassurance by the physician is helpful in keeping the patient satisfied with and faithful to his treatment. At the time of each check-up a hemoglobin determination and a guaiac test for occult blood in the stools are indicated. Repeated roentgenographic studies are not necessary in following a duodenal ulcer provided symptoms remain in abeyance. On the other hand, it is probably wise to observe the progress of a large duodenal

ulcer by repeating the x-ray studies about one year after the original demonstration of the ulcer

Gastric ulcers present a different follow-up problem because the possibility of neoplasm is ever present, even in gastric ulcers which show complete healing, as judged by disappearance of symptoms and of abnormal roentgenologic findings¹⁸ In such cases, the patient should be seen at monthly intervals for six months, at bimonthly periods for the next half year, and then every three months If symptoms, weight loss or occult bleeding occur, immediate reexamination by roentgenologic means is indicated If the patient remains asymptomatic, repeat x-ray studies should be performed every three months for one year Only by such careful observation can one decide whether one is dealing with a malignant or benign gastric ulceration

8 Preparedness—Some patients notice a seasonal incidence of their ulcer recurrences Others realize that their symptoms are often preceded by certain circumstances colds, emotional upsets, fatigue, and so forth Hence, the patient is advised to adopt a more intensive therapeutic regimen under the following conditions

- (a) At the beginning of a season which, on the basis of past experience, he associates with recurrent ulcer symptoms
- (b) Whenever he is suffering from an acute respiratory infection
- (c) Whenever he is severely fatigued, or when he is performing more than his usual amount of work
- (d) Whenever his emotional tension is heightened, as evidenced by insomnia, restlessness, increased irritability, or "nervousness"

The intensified regimen which is given to ulcer patients under the conditions listed above consists of

- (a) Strict adherence to the interval feedings and diet as given, except that coffee and citrus foods are eliminated completely
- (b) Tincture of Belladonna, 12 minims (0.8 cc) three times a day immediately after meals and at bedtime (Belladonna has been prescribed at various times with respect to meals, we give it immediately after meals in the hope that it may be effective at a time when ulcer symptoms occur one to two hours after food ingestion The optimum dose is one which barely causes a faint dryness of the mouth)
- (c) An antacid, consisting either of

(1) Aluminum hydroxide gel—2 drams (8 cc)

or

(2) A powder—1 dram (4 gm)

Calcium Carbonate

1 part

Magnesium Carbonate

1 part

Bismuth Subcarbonate

2 parts

To be taken one hour *after* meals and at bedtime

- (d) Increased physical rest earlier bedtime, rest on week-ends, cancellation of social activities and work which is not essential

The intensified regimen must be initiated *before* symptoms begin. By this means, circumstances which presumably play a role in precipitating a recurrent ulcer may often be prevented from bringing about their lamentable results. If symptoms arise in spite of all efforts to the contrary, the patient should notify his physician immediately.

TABLE 2—INSTRUCTIONS FOR THE PATIENT WITH A HEALED PEPTIC ULCER

Under certain circumstances, peptic ulcer can recur in persons who are subject to this disorder. You can reduce the chances of such a recurrence, however, by following these simple rules:

I. Stick to your diet. If you wonder whether a certain food is allowable, ask the doctor. Do not "test" foods to determine whether they cause symptoms or not.

II. Drink a glass of milk *regularly* half way between meals and at bedtime. You may take simple crackers with the milk if you so desire.

III. Your ulcer is particularly apt to recur

- 1 In the (physician fills in season of recurrence, if any)
2. When you have colds, sore throats, coughs. If you take medicines for these illnesses, take them with milk.
3. When you are physically fatigued or doing more than your usual amount of work.
4. When you are emotionally upset, or more irritable, sleepless or "nervous" than usual.

IV. Hence, whenever you are exposed to any of the circumstances listed under III, you should automatically take steps to prevent an ulcer recurrence.

1. Be very careful to observe points I and II.

2. Take 2 teaspoonfuls of _____ one hour after meals and at bedtime (4 times daily).

3. Take 12 drops of Tincture of Belladonna in a half a glass of water just after meals and at bedtime (4 times daily).

4. Go to bed earlier than usual. You do not necessarily have to sleep but it is important for you to get extra rest in bed. Rest on week ends. Cancel social activities and such work as is non-essential.

5. Observe this intensified form of treatment for at least one week. As a rule, it should be observed as long as the aggravating factors listed under III are present.

V. If you have any ulcer symptoms, notify your doctor immediately.

In addition to the diet, a printed list of instructions (an example is given in Table 2) can be given to the patient with advantage. For his memory of verbal instructions may fade with appalling rapidity.

SUMMARY

Although an uncomplicated peptic ulcer responds ~~readily~~ to sound medical treatment, ulcers will recur within five years in well over one half the patients. Therapeutic emphasis should ~~therefore~~ be placed on the prevention of recurrences. At present no specific ~~therapy~~ is available for this purpose. On the other hand, the ~~severity~~ severity of recurrent peptic ulcers can ~~often be reduced by a~~ be reduced by a strict regimen which opposes some of the ~~factors~~ ~~recurrent~~ ~~in the~~ ~~ulcer~~.

genesis of peptic ulcer, but which is not too arduous for the patient to observe

The proposed regimen embodies the following points (1) education of the patient, (2) psychotherapy, (3) dietary management with interval feedings, (4) regulation concerning alcohol, tobacco and exercise, (5) follow-up observations and (6) preparedness, so that the patient who is exposed to a circumstance known to aggravate peptic ulcer adopts an intensified therapeutic regimen *before* any symptoms develop

SPECIFIC THERAPY IN ACUTE HEMORRHAGIC NEPHRITIS

ALLAN M. BUTLER, M.D.* AND GERTRUD C. REYERSBACH, M.D.†

MANY years ago Volhard correctly emphasized that an appreciation of the dangers and therapeutic problem of acute hemorrhagic nephritis depended upon the recognition of the pathological process as consisting in a general as well as a renal vasoconstriction. By quoting him¹ we are not only reminded of the validity of his concepts but also of the length of time they have been at hand. "Thus in the acute stages we are dealing with a functional condition which endangers not only the kidney but also the other organs. In the acute stage it is the danger to the heart which is of first and highest importance. The danger to the brain is second, and to the kidneys only third. The danger that the functional condition in the kidney will lead to lasting and irreparable changes increases with the degree and duration of the general vasoconstriction manifesting itself by hypertension. The hypertension, caused by spastic narrowing of the small peripheral arteries, may set in suddenly even overnight. This means an enormous overload for the heart. Increased work can be accomplished only if the muscle fibers of the heart are stretched more than under normal conditions. A certain degree of dilatation of the heart thus is a necessary condition for increased work, but includes a danger of over-distention.

"The clinical picture of acute diffuse glomerulo nephritis, therefore, may present itself in the form of an acute and most severe insufficiency of the heart with dyspnoea of the highest degree, increase of the venous pressure and swelling of the liver. Almost every case that dies in the acute stage of the disease dies of cardiac insufficiency. Digitalis should be given in every such case.

"The second grave danger consists of cerebral edema, causing the convulsions of the so-called eclamptic uremia. This picture of so-called eclampsia, i.e., convulsive uremia, has nothing to do with true uremia caused by renal insufficiency.

"Convulsive uremia consists of increased intracranial pressure† and the equivalent utterances are headache, vomiting, apathy, somnolence and amaurosis. The higher the blood pressure the greater the danger to the brain.

From the Children's Medical Service, Massachusetts General Hospital and Department of Pediatrics, Harvard Medical School, Boston.

* Associate Professor of Pediatrics, Harvard Medical School. Chief, Children's Medical Service, Massachusetts General Hospital.

† Assistant, Department of Pediatrics, Harvard Medical School. Assistant, Children's Medical Service, Massachusetts General Hospital.

‡ Or cerebral ischemia due to vasoconstriction.

"For the success of the treatment the most important factor is that of time. Every day that a patient walks about without having his condition recognized renders the prognosis darker and diminishes the chances of complete ultimate recovery. It is, therefore, necessary to watch for nephritis after acute tonsillitis and other infections just as we are accustomed to do after scarlet fever. And we have to watch for it, not so much in the acute stage of these infections, as during the first two weeks following the fever."

Even today, Volhard's remarks can hardly be improved upon.

The vasoconstriction usually results in only functional disturbances. The responsibility of the physician is to institute therapy which will so limit the circulatory disturbances as to prevent not only sudden death in the acute phase, but also injury to parenchymal renal tissue resulting in irreversible and progressive kidney disease. In addition he must eradicate any residuum of the streptococcal infection which, as described by Longcope and associates,² is the etiologic agent of the acute disease.

The verification of vasoconstriction as the underlying physiological disturbance has been provided by Pickering³ and Rubin and Rapoport.⁴ The frequency of cardiac dilatation, myocardial failure and the efficacy of digitalis has been amply demonstrated.^{5, 6} The effectiveness of magnesium sulfate, first introduced by Blackfan and Mills,⁷ has been nicely described by Rubin and Rapoport.⁸ Winkler, Smith and Hoff⁹ have increased the effectiveness of this therapy by defining the relationship between therapeutic effect and the plasma magnesium concentration. Their data indicate that the desired vasomotor effect and fall in blood pressure are not obtained until the plasma magnesium has risen from the normal value of approximately 1.5 milliequivalents per liter to 5 meq per liter. As the concentration approaches 10 meq per liter, the tendon reflexes diminish, whereas respirations are not suppressed until the concentration has risen to between 10 and 15 meq per liter.

The purpose of this paper is to describe briefly (1) a typical case of acute hemorrhagic nephritis together with the therapy used in this clinic, (2) a case of acute hemorrhagic nephritis in which the clearly demonstrable clinical manifestations provide evidence that the abnormal physiologic disturbance is widespread vasoconstriction, and (3) a case demonstrating a progression of the acute functional vasoconstrictive stage to one of irreparable organic changes in the kidney with rapidly progressing renal disease which was arrested by recourse to a therapeutic procedure¹⁰ which, to our knowledge, has not been applied previously to such cases.

CASE I. TYPICAL ACUTE HEMORRHAGIC NEPHRITIS, ILLUSTRATING THERAPY

A 3½ year old boy was well until four weeks before admission when he vomited for twenty-four hours. Following this he developed a generalized red flush and a temperature of 103° F for one week. He never complained of a

sore throat. He then appeared well for two weeks. One week before hospitalization the child's face became swollen. He became fretful, vomited off and on and complained of headache and abdominal pain. He voided only small amounts of grossly bloody urine. It was noticed by the parents that the child became "short winded."

On admission to this hospital the patient was found to be a well developed, pale looking child with puffiness about the eyes and moderate generalized edema. The temperature was normal the pulse rate was 120 respirations were 26. He weighed $32\frac{1}{2}$ pounds. The skin was clear. The cervical glands were slightly enlarged. The ears, throat and nose failed to show signs of infection. The pupils reacted to light and accommodation. The fundi were normal. The neck veins were slightly distended. There was very slight dyspnea. The apex impulse of the heart was just outside the mid-clavicular line the heart sounds were of poor quality. The pulmonary second sound was louder than the aortic second sound. A blowing systolic murmur was audible at the apex, which was poorly transmitted to the axilla. The blood pressure was 140/110. The liver was felt three finger breadths below the costal margin and was tender. In spite of these signs of congestive failure, the lungs were normal to percussion and auscultation. Costovertebral tenderness could not be elicited. The extremities were normal except for slight edema the reflexes were in order.

The urine was acid with a specific gravity of 1.010 albumin 2 plus, no sugar, acetone or bile. The centrifuged sediment contained many red blood cells, a few white blood cells and occasional red cell, hyaline and granular casts per high power field. Urine culture showed no growth. The white blood count was 9800 with a normal differential count. The red blood count was 3,300,000 and the photoelectric hemoglobin 6 gm. per 100 cc. The blood nonprotein nitrogen was 34 mg and the serum protein 7.1 gm. per 100 cc.

X ray of the chest revealed a diffuse increased density extending from the hilar shadows into both lung fields consistent with congested blood vessels and pulmonary edema. There was a small amount of fluid in each pleural cavity. The heart was not definitely enlarged. An electrocardiogram was not taken.

A diagnosis of acute hemorrhagic nephritis, congestive failure and hypertension was made and the following treatment was instituted

1 Strict "cardiac" bed rest.

2 The diet was limited to 600 to 700 cc of sweetened fruit juice. The fluids are limited because of the oliguria and retention of fluid as evidenced by increase in weight and edema. The carbohydrate is given to minimize the utilization of body tissue for energy requirements and thus minimize renal work by reducing the urinary concentration and excretion of urea. We believe this initial dietary regimen is more logical than the complete fasting and thirsting recommended by Volhard.

3 The patient was digitalized with cedilanid, 0.3 mg being given on admission, 0.2 mg three hours later.

4 Phenobarbital, 32 mg., was given by mouth, as sedation not only favors relaxation and rest but also may result in a lessening of the hypertension.

5 After he was digitalized, the child received intravenously 3 gm of magnesium sulfate in 150 cc of 5 per cent dextrose in water (not in saline), over a period of forty minutes. During the infusion the child was observed for flushing of the face, nausea and diminution in

tendon reflexes and respirations. Two 10 cc ampules of calcium gluconate were ready at hand as an antidote to respiratory embarrassment due to the magnesium. The blood pressure was taken every five minutes, and was lowered from 150/90 to 130/50. The serum magnesium was at an effective concentration of 6.5 meq/l at the end of the procedure.

During the next three days the blood pressure ranged between 120 to 100 systolic and 80 to 60 diastolic. The signs of congestive failure had disappeared the morning after admission but the heart remained overactive. Digitalization was continued by mouth, 36 mg USP digitalis being given daily.* The child voided well and lost 2 pounds in weight. The daily fluid intake was liberalized to 1000 cc. All seemed to be going well when on the fourth day the blood pressure rose to 150/100. The child became fretful and complained of abdominal pain. The heart was very overactive and the liver edge was palpable 2 cm below the costal margin, but was not tender. Sedation with phenobarbital was continued. Magnesium sulfate, 3.2 gm in 160 cc of 5 per cent dextrose in water, was given intravenously. The blood pressure at the beginning of the infusion was 154/92 and 122/65 at the end. The serum magnesium concentration was 5 meq/l directly after the infusion.

The next morning, the blood pressure was again 156/96. Four grams of sulfate were infused between 10 and 11 A.M. with a drop in the blood pressure to 115/64. One hour later, 2.5 gm of magnesium sulfate were given by mouth. Two hours later (2:00 P.M.), the serum magnesium was found to be at the therapeutically inadequate concentration of 3.6 meq/l. The blood pressure again rose to 150/90. Four cubic centimeters of a 25 per cent solution of magnesium sulfate was given intramuscularly and 2.5 gm were given by mouth at 4 P.M. At 6 P.M. the serum magnesium was only 3.5 meq/l. Thus the oral and intramuscular magnesium had not maintained the serum magnesium at an effective level. The blood pressure then was 138/84.

Thereafter the blood pressure dropped to normal levels with but an occasional rise for a short period. The maintenance dose of 36 mg of digitalis was given daily for a period of twelve days, being omitted on the seventh day to avoid a cumulative effect. The child lost another 2 pounds in weight. Fluids were permitted as desired. The diet was gradually liberalized, but protein was limited to 30 gm daily and no extra salt was given. Supplemental vitamins A, D, C and B's, and Feosol were provided. From the eleventh hospital day on, the child was entirely comfortable. At that time the lungs were clear by x-ray. An electrocardiogram was within normal limits. The white blood count

*The maintenance dose is roughly one-tenth of the twenty-four hour digitalizing dose, the latter being approximately 33 mg per kg of body weight. In the oliguric edematous nephritic, the urinary excretion of the digitalis may be less than normal and hence care must be taken lest such patients be overdigitalized.

and temperature remained within normal limits, x-rays of the sinuses failed to show sinusitis and throat cultures on admission were negative. The rigid restriction of activity was relaxed.

After three weeks in the hospital, the urine was clearing satisfactorily and the hemoglobin began to rise. The erythrocyte sedimentation rate stayed around 45 mm./hr. by the Westergren method.¹¹ Tuberculin 1:1000 was negative and a Hinton test was negative.

At the end of the fourth week the child was placed on a normal diet for age and discharged to a convalescent home where normal activity was gradually resumed and recovery was apparently complete.

CASE II DRAMATIC MANIFESTATIONS OF A GENERALIZED VASCULAR DISTURBANCE

An 11 year old school boy entered the hospital with a chief complaint of dizziness, disorientation and paralysis.

Eighteen days before admission to the Massachusetts General Hospital the boy complained of a headache. It was noticed that his eyes were puffy and trunk edematous. The urine was dark brown. Two days later the child had a generalized convulsion which started in the left arm and lasted 10 minutes. The boy was admitted to another hospital. The record is of interest because of the initial diagnosis, the repeated lumbar punctures and the lack of specific therapy for the underlying disturbance.

On admission there, the boy was conscious and responded to painful stimuli. Blood pressure was 150/110. The urine contained albumin, red blood cells and casts. The blood nonprotein nitrogen was 65 mg. per 100 cc. Shortly after entry the child had three more convulsions. During the night and through the early morning he continued to convulse; none of the seizures lasted more than one minute except for one which lasted two minutes. The child was irrational and incontinent and developed Cheyne-Stokes respirations. Sodium luminal, 2 grains, and 5 per cent glucose intravenously failed to give relief. A lumbar puncture was done revealing an initial pressure of 210 mm. and a final pressure of 175 mm. of water. The clear spinal fluid revealed 116 white blood cells per cubic millimeter with 63 per cent polymorphonuclears, no red blood cells, 2 plus Pandy and sugar of 103 mg. per cent. The smears showed no organisms. It was the impression of the neurological consultant that the child had a meningitis of undetermined type. He advised sulfadiazine therapy* and repeated lumbar punctures. The spinal fluid and blood cultures were negative. The child remained semi-comatose for three days, then became rational. He had a paralysis of the left arm for one or two days and then developed a right-sided paralysis. He was aphasic. After eight days the blood pressure had fallen to 112/74; the urine continued as before. The paralysis as well as the aphasia were improving some what on the tenth hospital day when the child was taken home by the parents.

During the next six days at home he appeared to improve. The following day he complained of dizziness, became disoriented and on the following day was brought to the Massachusetts General Hospital on the advice of the family physician.

Examination revealed a well developed but poorly nourished boy of eleven. He was in no distress. He knew his name, but not his age or how many brothers and sisters he had. The identification of objects was poor. The child stated that

* A hazardous therapy in the presence of hematuria and particularly so when this is accompanied by the oliguria so frequently present in the initial phase of acute hemorrhagic nephritis.

he "had forgotten many things" and was apparently aware of his mental defect. The temperature was 99° F. There were no signs of an upper respiratory infection, the pupils were equal and reacted to light and accommodation, and the fundi were normal. The heart was not enlarged, the sounds were of good quality. A soft systolic murmur was present at the pulmonic area. The blood pressure was 95/60. The lungs were clear to percussion and auscultation. The liver was not enlarged. A right flaccid paralysis was present, more pronounced in the arm than in the leg. The deep reflexes were more active on the right.

The white blood count was 11,500 (polymorphonuclear 65 per cent, lymphocytes 23 per cent and monocytes, 12 per cent), the red blood count 4,600,000

Fig 168 (Case II)—Boy 11 years of age. Electrocardiogram on admission to Massachusetts General Hospital. Rate 75. P-R interval 0.13 sec, normal axis, inverted T_1 , upright T_2 and T_3 , chest leads deeply inverted T in CF_2 , inverted T in CF_4 , biphasic T in CF_5 . The tracing is consistent with the diagnosis of anterior myocardial infarction near the septum.

and the hemoglobin 12 gm per 100 cc. A urine specimen showed a specific gravity of 1.018, albumin 2 plus, no sugar, acetone or bile. The centrifuged sediment contained many red blood cells, 3 to 5 white blood cells and rare red cells and granular casts. The absence of many white blood cells and epithelial cells and the presence of normal concentrations of serum protein, nonprotein nitrogen and cholesterol suggested no extensive damage to parenchymal renal tissue. A normal serum chloride suggested no residual renal damage due to sulfonamide therapy.¹² A Hinton test of the blood was negative and tuberculin 1:1000 was negative.

The heart by x-ray was not definitely enlarged. There was no evidence of pulmonary edema.

A diagnosis of acute hemorrhagic nephritis with cerebral accident due to the hypertension of acute phase was made. In order to deter-

mine any persistence of myocardial involvement, an electrocardiogram was taken which, much to our surprise, showed a tracing which was interpreted by Dr Paul D White to be characteristic of anterior myocardial infarction close to the interventricular septum. Electrocardiograms taken weekly showed gradual healing of the infarction.

As the vascular disturbance of the acute nephritis seemed to have subsided, no specific therapy was given. Under physiotherapy the paralysis improved and the aphasia remained about the same. At the time of discharge, eight weeks after admission, the boy had gained six pounds, the sedimentation rate was normal.

In all probability this patient's convulsions could have been stopped at the time of admission to the first hospital and prevented thereafter, if an appropriate infusion of magnesium sulfate had been given promptly and repeated as indicated. The question as to whether prompt and adequate specific therapy would have prevented the sequelae cannot be answered so assuredly, but certainly the question is worth raising.

CASE III PROGRESSION IN ABSENCE OF EARLY SPECIFIC THERAPY

Three months before admission D L., a 12 year old boy developed a sore throat followed by bilateral purulent otitis media. At the same time his younger sister had unquestionable scarlet fever. The otitis media was treated with sulfonamides and cleared up. One week later the right ear began to discharge again. The urine became murky and the mother noticed facial edema. The child complained of abdominal pain. The family physician found a blood pressure of 160/90 and "blood in the urine." The patient was put to bed at home and treated for six weeks with a salt free diet without specific therapy. His urinary output was good but the urine continued to contain albumin, red cells and many casts. On development of a right mastoiditis he was admitted to another hospital.

A summary of that hospital's record showed the following. The admission temperature was 101° F. Red blood count 3.4 million, hemoglobin 70 per cent, white blood count 20,000 with 85 per cent polymorphonuclear cells. The urine contained albumin, red cells and many casts. The nonprotein nitrogen of the blood was 62 mg per 100 cc. Cultures from the ear grew *Staphylococcus aureus*. X rays of the right mastoid region showed increased density and some decalcification but no evidence of cell destruction. Penicillin (12,000 units every three hours intramuscularly) was given as the chemotherapy of choice in the presence of nephritis and hematuria. The temperature and white blood count fell to normal. The mastoid symptoms subsided as did the discharge from the ear. His anemia was improved by a transfusion. However the urine findings remained unchanged and the blood nonprotein nitrogen stayed elevated. The urine volume decreased and he again developed edema of the face and hands. He was then transferred to the Massachusetts General Hospital, eleven weeks after the onset of the hematuria and edema.

Physical examination on admission revealed temperature 99° F; blood pressure 170/104 and weight 73½ pounds. The boy was in no distress. He had minimal generalized edema. The ear drums were normal and he had no signs of an upper respiratory infection. The fundi were negative. The heart was not enlarged. The rate was 70. Murmurs were not heard. The percussion note was flat at the base of both lungs. The liver was palpable just below the costal margin. The remainder of the physical examination was not remarkable.

The red blood count was 5 million, hemoglobin 98 per cent, white blood count 15,000, polymorphonuclears 72 per cent, lymphocytes 24 per cent and monocytes 4 per cent. The urine had a specific gravity of 1.010, albumin 3 plus, no sugar, acetone or bile. The centrifuged sediment contained many red blood cells, 10 to 15 white blood and epithelial cells and numerous granular and hyaline casts per high-power field. The urine culture was negative. Chest x-ray showed the heart was not unusual as to size or shape. There was no definite evidence of pulmonary edema but there was fluid in both pleural cavities. There was haziness of the right mastoid, but no bone destruction. An electrocardiogram was within normal limits. The serum nonprotein nitrogen was 33 mg., protein 5.1 gm., inorganic phosphorus 7.5 mg and cholesterol 357 mg per 100 cc. This diminution of serum protein and elevation of phosphorus and cholesterol together with character of urine sediment were indicative of a progression of the nephritis from an

Fig 169—Photomicrograph of renal biopsy (Case III) removed at first operation showing capillary endothelial proliferation and avascularity of a glomerular tuft, and well marked subcapsular extracapillary epithelial proliferation (Courtesy of Dr Benjamin Castleman)

acute reversible stage to a chronic progressive type. A urea clearance test was 15 per cent of normal. Though this might actually have been somewhat greater, as the rate of urinary excretion was low, this degree of reduction of urea clearance eleven weeks after onset of the nephritis confirmed the presence of sub-acute parenchymal damage.

Intravenous pyelograms showed rather large kidneys in which dye became visible only after one hour.

The patient's temperature remained normal. His urine output was poor and he gained weight steadily. Because of the elevated white blood count and the possibility of residual streptococcal infection, the boy was given sulfanilamide for five days and then penicillin intramuscularly for ten days. As usual when the nephritis has passed beyond

the acute functional stage, the hypertension was lessened only slightly and briefly by magnesium sulfate given intravenously, intramuscularly and orally. The child vomited off and on and complained of dimness of vision. He developed papilledema with retinitis. The blood non-protein nitrogen rose to 41 mg per 100 cc. The serum inorganic phosphorus rose to 8.3 mg with the serum calcium falling to 5.5 mg and the serum protein to 4 gm. per 100 cc.

On the fourteenth hospital day decapsulation of the right kidney was done expeditiously. This procedure, which we hardly ever employ, was resorted to in this case because of the very marked oliguria, the large edematous appearing kidneys by x-ray and the hope that a diminished intrarenal pressure and hence improved volume of urine might follow decapsulation. A renal biopsy was taken at that time. As was consistent with the clinical course, a microscopic section showed a very extensive glomerular nephritis progressing from an acute to a chronic stage (Fig. 169). Following the operation the volume of urine increased somewhat, but the blood pressure remained elevated and the nonprotein nitrogen rose to 51 mg per 100 cc. The patient again developed anemia, the serum protein fell to between 3 and 4 gm per 100 cc. and he had massive edema. Because the prognosis appeared hopeless without interference, it was decided, in consultation with Dr. Reginald Smithwick, to do bilateral sympathectomies.¹⁰

Left-sided lumbodorsal sympathectomy with decapsulation of the left kidney was performed by Dr. Smithwick on the thirtieth hospital day. Following this the blood pressure remained elevated. Four days after the operation the blood pressure rose to 250/160 and the child suffered a severe hypertensive cerebral crisis with unconsciousness and generalized twitchings. A lumbar puncture done at this time showed a normal spinal fluid with an initial pressure of 140 mm of water. Following the intravenous administration of 6 gm. of magnesium sulfate in 300 cc. of 5 per cent dextrose in distilled water the blood pressure fell to 160/130 and the patient became responsive.

During the next few days the edema increased necessitating an abdominal paracentesis and a thoracentesis. The blood pressure ranged between 240 to 200 systolic and 160 to 140 diastolic. The patient developed mild congestive failure and was digitalized. The calculated dose, 1 gm. of digitalis or 33 mg per kilo body weight, was administered within a period of 36 hours in six divided doses. A maintenance dose of 100 mg was given every other day for a period of two weeks. The edema of the disks and retinitis increased.

The right lumbodorsal sympathectomy was done three weeks after the left. Within two days the blood pressure had leveled off at 150/100. The massive edema persisted. A weight of 93 pounds was 20 pounds above the admission weight. The serum protein remained at 3 gm. per 100 cc. The blood nonprotein nitrogen fell to 36 mg., the serum inorganic phosphorus dropped to 5.3 mg and the serum calcium rose to 7 mg per 100 cc. The urine continued to contain 3 plus albumin, 10 to 15 red blood cells and 5 to 10 white blood cells and many granular casts per high power field. The fundi improved somewhat.

The boy was discharged after a four months hospital stay on a normal diet supplemented with two tablespoonfuls of "amigen." These amino acids were given as readily assimilated protein constituents with the hope of improving the

protein and general nutrition At the same time, because of the danger of nitrogen and phosphorus retention in the plasma, provision was made to follow the serum concentrations of these elements Vitamin D, 2500 I U daily, and one half teaspoonful of B complex three times a day, 15 gm of sodium lactate three times a day and 0.5 gm ferrous carbonate twice a day were also prescribed

When the boy was re-examined five months later he had lost his edema, was up and about and felt well Blood pressure was 120/80 The urine still contained much albumin The spun sediment showed many white blood cells, a fair number of red blood cells and rare casts The nonprotein nitrogen was 25 mg., serum protein 3.6 gm., calcium 7.6 mg and phosphorus 5.2 mg per 100 cc., the phosphatase was 3.4 Bodansky units and chloride 109 meq per liter One year later he continues to feel well The serum protein has risen to 5.8 gm per 100 cc A slight rise in nonprotein nitrogen suggests reducing the nitrogen intake

Here, too, the question may be raised as to whether the prompt institution of therapy to arrest the circulatory disturbance would have prevented irreversible damage to the kidneys The course from completion of the sympathectomy to the present time recommends, in our opinion, future resort to this type of surgical therapy in such cases

COMMENT

Perhaps these case histories, by illustrating the physiologic disturbances of acute hemorrhagic nephritis, together with their specific therapy, may provide evidence that patients suffering from this condition deserve more than bed rest, "bland" diet and a too frequently purposeless tonsillectomy Volhard¹ has aptly said "To the practicing physician one of his most important tasks is the treatment of acute diffuse glomerulonephritis It imposes a great responsibility but may also bring the greatest satisfaction"

MANAGEMENT OF THE PATIENT WITH CHRONIC DIFFUSE GLOMERULONEPHRITIS

STANLEY E. BRADLEY, M.D.*

GENERAL CONSIDERATIONS

Pathological Factors—The unique position of the kidneys in the body economy is responsible for the difficult therapeutic problems of chronic diffuse glomerulonephritis. These organs play a controlling role in cardiovascular dynamics, in the regulation of body water and electrolytes, and in the excretion of the waste products of metabolism. Glomerulonephritis disrupts these functions by interference with glomerular filtration, destruction of tubules, and distortion of the renal vascular bed. Therapy is concerned, primarily, with the correction and alleviation of the pathophysiologic phenomena that result from the structural alterations. No means of halting the disease process is yet at hand. There is general agreement that the course of chronic diffuse glomerulonephritis may be broadly divided into three stages. The first and earliest stage—the *latent stage*—distinguished by minimal and irregular proteinuria, occasional hematuria and a tendency to slight dependent edema or morning facial edema may appear *de novo* or upon the heels of an episode of acute diffuse glomerulonephritis. With further glomerular damage, proteinuria increases and the patient enters the *nephrotic stage* of excessive urinary protein loss, hypoproteinemia, and massive edema formation. Finally, if the process is not arrested by death or reversal, arterial hypertension and renal insufficiency develop in the *terminal stage* of the disease. Although this train of events is commonly seen, in any given instance only one stage may ever be seen or two may occur simultaneously.

Psychosomatic Factors—Individuals in whom the disease is discovered accidentally in the course of a casual examination often undergo a rather harrowing experience. In the midst of apparent health, they suddenly find themselves placed apart from other normal persons by their inability to obtain insurance. There are repeated urinalyses, blood chemistry studies, and tests of one type or another. For many people, this sudden diagnostic activity betokens a serious and perhaps fatal illness. Often they even begin to feel unwell and unless reassurance is skillfully practiced, an extraordinary amount of unnecessary mental suffering may result.

From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston, Massachusetts.

* Instructor in Medicine, Boston University School of Medicine, Assistant Physician, Evans Memorial, Massachusetts Memorial Hospitals.

As a first step in establishing a basis of security, it is necessary to outline for the patient some intelligible account of the disease of which he is a victim, the necessity for the various diagnostic procedures he must undergo, and the objectives of therapy. It is well to remember that prognosis early in the disease may always be optimistic and even in the later stages may be hopeful, since it is known that the process may be arrested spontaneously and permanently, as late in the course as the nephrotic stage, and that even far-advanced renal disease is not inconsistent with several years of life.

In the nephrotic stage of the disease, the huge accumulation of fluid in the tissues may make activity impossible. Alone and immobilized, such patients may become deeply depressed. The radio and occupational therapy are as vital in obtaining good results as efforts to repair the physiological defect at fault. Hope can be offered honestly since it is usual for edema to regress, whether this is a result of further renal damage or of healing.

In the terminal stage, hope should not be denied the patient, but the family should be informed of the hopelessness of the situation. With proper care and good fortune many may live several years. Although protective measures must be taken, it is unfair to forbid all possibly injurious, but enjoyable, activities.

MANAGEMENT OF THE LATENT STAGE

It is best to advise the patient in this stage to forget his illness and live a normally quiet life. Dietary restrictions are unnecessary and may even be harmful. Of course, it is unwise for these patients to expose themselves to cold and exhaustion, since acute exacerbation of the renal disease is an ever-present threat. Focal infection should be eradicated under the protection of sulfonamide pretreatment, but indiscriminate tonsillectomy is to be condemned.

Minimal edema may be very annoying. Young women, in particular, complain of this phenomenon because slight edema of the lower extremities quickly produces an unpleasant cosmetic effect and uncomfortably tight shoes. This may be relieved by periods of rest with the feet elevated and a salt-poor diet, together with moderate water restriction.

MANAGEMENT OF THE NEPHROTIC STAGE

At this stage of the disease, renal function is usually but slightly impaired. The chief problems are removal of excess body fluid and replacement of the plasma protein. As renal damage increases, many patients imperceptibly enter the terminal stage of outright renal insufficiency and systemic arterial hypertension. Frequently, no clear-cut dividing line is discernible and for a space the two stages overlap. For purposes of clarity the two will be considered as distinctly separate entities in this discussion.

Plasma Protein Replacement—Since fluid accumulates in the inter-

stitial spaces as a result of the reduction in plasma proteins, and since albumin makes up the largest portion of the lost protein, the administration of albumin concentrates in sufficient quantity to replace losses seems to be the most logical procedure. Recent experimental work indicates that the proteins of the body are more or less interdependent, comprising a single "pool," the components of which are in equilibrium. Withdrawal of protein from one region (the blood, for example) results in changes of concentration in all areas due to shifts in the reestablishment of equilibria thus disturbed. Consequently, the hypoproteinemia of nephrosis cannot be thought of as a phenomenon limited to the vascular bed, but must be considered part and parcel of a derangement affecting protein stores all over the body. In like fashion, the administration of protein does not result in a contribution of protein to the blood alone but to the total protein pool. The size of this pool, since it includes every area of the body, is enormous and protein concentration in it is not easily affected by doses administered with ease to man. Sachar and his co-workers¹⁰ have shown that the ratio between extravascular and vascular protein in the protein starved dog is of the order of magnitude of 25 to 1. This means that 25 gm of protein must be given to replace 1 gm in the plasma. Probably the ratio is not as large in the nephrotic syndrome in man but even if it is assumed to be 10 to 1, 300 gm of protein must be given to increase the plasma concentration by 1 gm per 100 cc of plasma (assuming a plasma volume of 3000 cc). Obviously, such a dose is impractical. Moreover, albumin concentrates are not yet generally available to the practitioner and only materials in which the protein concentration is relatively low, such as whole blood and plasma, can be used. The fact that immediate and rapid reversal of hypoproteinemia is impossible with the means at hand does not mean that such measures are valueless. At least, urinary protein loss can be compensated for on a gram-for-gram basis in this manner, and diuresis may be stimulated.

Diet—For the majority of patients in the nephrotic stage, intravenous replacement of protein is impractical because it is rarely necessary for such patients to be confined to the hospital. For these people, and for bedridden patients as well, dietary measures may prove invaluable. The protein intake must be increased to the point where urinary loss is exceeded. In time, such a diet may result in marked clinical improvement. A sample diet containing 125 gm of protein per day is presented in Table 1. The instructions to the patient should be noted. Salt and water restriction are imperative in the fight against edema formation. Moreover, an attempt to insure appetizing preparation is worth-while, since anorexia may be a serious problem. Adequate vitamin intake is, of course, of great importance. In addition, protein manufacture can be supported and enhanced by intravenous or oral administration of protein digests or amino acid mixtures, such as Amigen and Parenamine.

Diuresis.—Although whole blood and plasma transfusions cannot change the plasma protein level significantly, diuresis may be induced by them. The transmembrane protein shifts by which added protein is distributed through the total body protein pool are necessarily slow. During the period of adjustment, the plasma level of protein does rise significantly and even if this elevation is transient, it is of important beneficial influence. The transient elevation of plasma protein increases

TABLE 1 —DIET IN THE NEPHROTIC SYNDROME

Sample Form

Diet for M.

It is necessary for you to eat more meat and other protein-containing food because you are losing protein in your urine every day. In addition, your kidneys cannot remove as much water and salt as normal kidneys. Consequently, you must cut down the amount of water and salt you take to avoid water logging your body. The diet below is a sample diet for one day. Substitutes are mentioned. Be sure that your food is cooked without salt and do not use salt at meals.

Breakfast	Fruit	1 serving
	Cereal	(cooked) $\frac{1}{2}$ cup
	Eggs	2
	Bread	1 slice with butter
	Milk	1 glass
	Coffee	As desired with cream and sugar
Luncheon	Meat, fish or poultry	1 extra large serving (4 oz.) may substitute 2 eggs and 1 oz. cheese
	Potato	1 (or other vegetable)
	Vegetable or fruit salad	
	Bread	1 slice with butter
	Milk	1 glass
	Dessert	Choice from list on dinner menu
Dinner	Meat, fish or poultry	1 extra large serving
	Potato	1 (or other vegetable)
	Vegetable	2
	Bread	1 slice with butter
	Milk	1 glass
	Dessert fruit	1 (or sponge cake, angel cake, fruit whips made with egg white, and fruit served with custard sauce, baked custard, or gelatin desserts)

Drink no more than 5 glasses of water each day

the oncotic pressure of the plasma. Water is withdrawn from the interstitial compartment in large amounts, flooding the vascular bed and diluting the constituents of the blood. This dilution brings into operation mechanisms by which excess plasma water is excreted by the kidney, and a diuresis results. If the situation is borderline, this may be sufficient to set in train a series of restitutive processes by which edema is lost. However in most instances, the protein in the blood slowly falls as a result of loss into the tissue protein pool. The diuresis slackens and finally ceases.

Other diuretic agents, a list of which is given in Table 2, have proved of value in reducing edema. On the whole, these agents act, in one way or another, to increase the osmotic pressure of tubular urine. Urea is probably as effective as any. Some patients object to the taste but, for the most part, it is taken unprotestingly. Mannitol has proved an excellent diuretic in our hands. No toxic effects have been observed and a marked diuresis may be induced. Unfortunately, it must be administered by the intravenous route. Both mannitol and urea appear to be nontoxic under almost any circumstances, but this cannot be said for the other substances listed in Table 2. Potassium salts have found enthusiastic use,⁶ but the presence of renal insufficiency makes possible dangerous retention of the toxic potassium ion. Ammonium chloride, too, is popular but this may precipitate a chloride

TABLE 2 —DIURETICS

	Dose	Comments
Urea	60 gm per day	Give in divided doses in cold fruit juice
Mannitol	25-50 gm per day	Given intravenously in 25 per cent solution (Sharpe and Dohme) 2-4 divided doses
Potassium chloride	5-10 gm per day	Divided doses. Never use in presence of renal insufficiency
Ammonium chloride	8-12 gm per day	Divided doses. Never use in presence of renal insufficiency or acidosis
Mercupurin	1-2 cc per day	May be given intravenously or intramuscularly. Best response following preparation with ammonium chloride. Never use in renal insufficiency or in presence of diluting impairment

acidosis if caution is not exercised. Finally, mercuripurin and other mercurials have been advocated as extremely effective agents. This is particularly true if the patient has had a course of ammonium chloride therapy. Mercurials appear to induce a chloride diuresis and marked chloride loss may result if an adequate chloride intake is not maintained. A second and greater danger of mercurial medication arises from the potential nephrotoxic action of these drugs.

In certain types of the "nephrotic syndrome" in chronic diffuse glomerulonephritis, impairment of diluting power may be associated with azotemia.

S. H., a 34 year old Chinese, whose course is charted in Figure 170, was such a patient. He was admitted to the Evans Memorial suffering from anasarca, ascites and hydrothorax of four weeks' duration. He presented the classical signs of the nephrotic syndrome, including a marked hypoproteinemia, hypercholesterolemia, and heavy proteinuria. Renal function studies* revealed a greater re-

* Mannitol and *p*-aminohippurate were generously supplied to us for these and other studies by Sharpe and Dohme, Inc. For details of clearance procedures see Goldring and Chasis.⁵

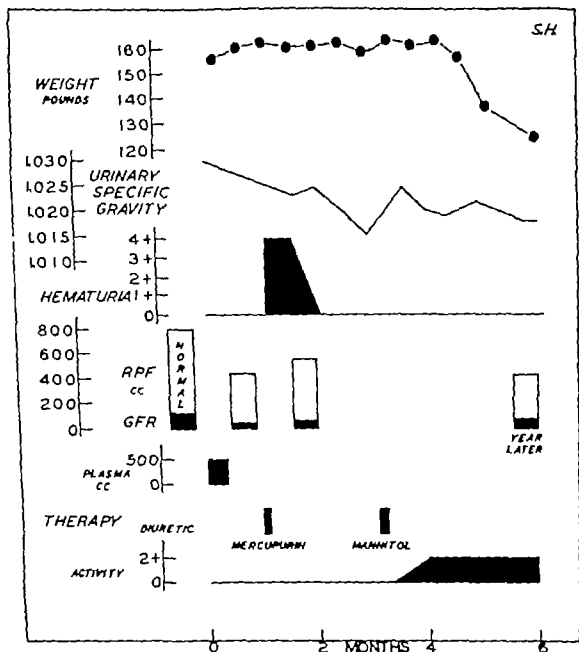

Fig 170—Clinical course and therapy of chronic diffuse glomerulonephritis in the nephrotic stage complicated by azotemia and renal incapacity to secrete dilute urine. S H., a 34 year old Chinese male, was admitted with anasarca, ascites, and hydrothorax of four weeks duration with no previous history of renal disease. Glomerular filtration rate (G.F.R.—mannitol clearance) was reduced to a greater extent than the renal plasma flow (R.P.F.—*p*-aminohippurate clearance). Nonprotein nitrogen, 74 mg per 100 cc plasma proteins, 3.64 gm. per 100 cc. cholesterol 353 mg. per 100 cc. and a persistent proteinuria were among the laboratory findings not charted above. Plasma transfusions failed to produce any change in the clinical or laboratory picture. Mercupurin induced gross hematuria and did not provoke diuresis. Mannitol likewise, was ineffectual. A course of thyroid extract (not charted) following mannitol therapy produced no change and was discontinued. A gradual improvement of the clinical picture spontaneously without significant change in blood chemistry permitted reactivation. At present the patient's weight remains at about 130 pounds. Renal function continues to be impaired and other laboratory findings are not significantly altered. Edema rapidly reaccumulates if he deviates from a strict regimen of limited activity, salt and water restriction, and high protein diet. This case demonstrates the danger and ineffectuality of diuretic measures in the nephrotic syndrome in the presence of azotemia and a fixed high urinary specific gravity.

duction in the glomerular filtration rate—GFR (measured by the mannitol clearance)—than in the renal plasma flow—RPF (measured by the *p*-aminohippurate clearance)—a functional pattern¹ consistent with the diagnosis of chronic diffuse glomerulonephritis. In addition, the urinary specific gravity remained persistently elevated and a moderate azotemia was present throughout the course in the hospital.

The patient was placed at bed rest and transfusions of plasma were given daily over a period of ten days without demonstrable change in plasma protein concentration or clinical appearance. Next, mercupurin was administered in the hope of inducing diuresis. Not only did it fail to do this, but definite renal damage resulted in grossly bloody urine. Gross hematuria persisted for a matter of two weeks or more. A third attempt to induce diuresis failed likewise, when mannitol was administered intravenously several weeks later. A course of thyroid extract (0.06 to 0.12 gm. per day) appeared to have little effect. Finally, facial and scrotal edema slowly cleared, without significant weight change, probably as a result of fluid shift to other areas. Then, after approximately four months of bed rest and high protein diet, the edema began to clear, the weight dropping slowly over a two months period to a new constant level, about 40 pounds below the admission weight. During this period he was gradually reactivated without any effect on the process of fluid loss.

On discharge, the patient's lower extremities were still edematous and have remained so to the present. There has been little change in renal function (aside from some improvement in the glomerular filtration rate), urinary protein loss, or plasma protein concentration. The urinary specific gravity over a period of more than one year following onset of the illness has gradually fallen to an average level of 1.015. Azotemia continues to be present.

This case teaches several important lessons. First, diuretic therapy in the presence of a high urinary specific gravity and persistent azotemia is ineffectual and contraindicated. The use of mercupurin in this instance produced further renal damage. The failure of the kidneys to respond to urea, present already in high concentration in the blood, should have been sufficient evidence that other diuretics would be ineffectual. Secondly, the spontaneous regression of edema teaches caution in attributing curative effects to any diuretic or other agents in this disease.

Risks and Protection—Inherent in the nephrotic syndrome are the risks of infection of the water-logged tissues and body cavities and of the curious condition known as "the nephrotic crisis." These patients are peculiarly prone to infection by the streptococci and pneumococci. Erysipelas and peritonitis occur frequently and suddenly. Conventional therapy with sulfonamides and penicillin is indicated as well as supportive measures such as transfusion. The presence of glomerulonephritis does not contraindicate the use of the sulfonamides, but they should be used cautiously since additional renal damage is to be feared. In the presence of renal insufficiency, it is likely that the inability of the kidney to excrete concentrated urine prevents a dangerous concentration of sulfonamide in the tubular urine. In the nephrotic stage, particularly in cases like S. H. described above, the danger is greater. Since excretion may be less rapid than normal, dangerously high blood

levels may be attained very rapidly with relatively small doses. Hence, frequent determination of the blood level is necessary. The initial dose of any sulfonamide need differ in no way from that commonly used, but sustaining doses must be reduced greatly, depending upon the blood level obtained. Penicillin, too, may be given in smaller daily doses because excretion is reduced.

The "nephrotic crisis" is characterized by a sudden onset of a sterile or bacterial peritonitis associated with a marked hypoaminoacidemia. Farr² and others³ have shown that the fatality rate can be greatly reduced by intravenous administration of amino acids. Amino acids may be given intravenously as Amigen (Mead Johnson)—one to two liters of 5 per cent solution in 5 per cent glucose daily—or Parenamine (Stearns)—one bottle (100 cc.) in one liter of 5 per cent glucose, one or two times each day. Amino acid mixtures must be given slowly to avoid unpleasant saline reactions of flushing, nausea and vomiting.

Life is restricted, of necessity, for these patients. The rapid appearance of massive edema of the extremities after long standing denies to them occupations in which this is necessary. A sedentary life is forced upon them by the disease rather than by the physician. Nonetheless, a useful and happy life may be assured by careful routinization, by dietary precautions, and by proper use of available therapeutic measures.

MANAGEMENT OF THE TERMINAL STAGE

In general, the phenomena manifested in this stage are of either renal or circulatory origin. In many patients a complex of signs arises in part from both types of disorders. In the present discussion, problems that result from hypertension will not be discussed and renal manifestations will be considered as pure states. It cannot be emphasized too strongly that this is a departure from the truth in most instances, since pure states are rare. Simplified formulation of therapy may be misleading if this fact is overlooked.

Each patient must be treated individually in the light of a full knowledge of both the circulation and the kidney, and of the degree to which disorders in each infringe upon and complicate disorders in the other. Complete analysis of the patient's physiological status is necessary. The body water electrolytes can be estimated by determination of plasma carbon dioxide combining power, chloride, calcium and phosphorus, and chemical imbalance calculated roughly from these facts. The state of hydration must be evaluated from clinical signs, from the history, and from the study of the water balance. Occasionally the hematocrit is helpful, but since most of these patients are anemic, interpretation is often difficult. A knowledge of the plasma protein is always helpful. Electrolyte and protein loss may require quantitation of daily loss in the urine, so that adequate replacement may be possible. There are many more complicated procedures by

which a clearer picture may be drawn, but those mentioned are generally available and extremely useful

Dehydration—When damage to both glomeruli and tubules becomes very severe the functional balance between the glomerulus and its attached tubule is lost. Many nephrons become permanently diuretic as a result of a glomerular filtration rate beyond the capacity of tubular water reabsorption. The failure of water reabsorption may lead to marked water and electrolyte loss. Most patients respond to the drain by increased water intake, but occasionally the thirst mechanism may be impaired. In these cases, dehydration may develop insidiously. All patients in this stage of the disease should be warned of the increased need for water and increased intake prescribed. Polyuria and nocturia, that prove annoying and even exhausting, develop. If nocturia is so profuse as to interfere markedly with rest, a regimen of water intake designed to produce the greatest output in the waking hours of the day should be laid out. Chloral hydrate (0.5 to 1.0 gm.), phenobarbital (0.03 to 0.06 gm. or 4 cc. of the elixir) and other hypnotics are of value in sedation when they are given during the course of the day or in the evening at bedtime.

When water loss is aggravated by diarrhea and vomiting, dehydration may be profound. Under these circumstances, oral replacement may be impossible or inadequate, and fluid must be given by vein. Table 3 summarizes briefly the important forms in which fluid and electrolytes may be administered parenterally. Gluco-saline (equal parts of isotonic saline and 5 per cent glucose solution) is particularly valuable in combating dehydration in renal insufficiency because there is no need for renal adjustment of electrolyte balance. However, the administration of electrolyte must be adjusted to particular needs in individual cases. Hence, any generalization regarding fluid replacement alone is impossible.

Electrolyte Imbalances—When water is lost from the body there is always concomitant loss of electrolyte. The extent and character of electrolyte loss depends upon the site of water loss and many other factors. In the terminal stage of chronic diffuse glomerulonephritis, electrolytes may be retained as well as lost and any conceivable electrolyte pattern may develop.

Anion Loss—In one type of the disease, sodium-sparing devices appear to respond more or less normally, despite severe renal damage that otherwise, leads to diuresis and chloride loss. Perhaps, also, chloride reabsorption is impaired. In any case, chloride ion and water are swept out of the body in a persistent diuresis and a syndrome, resembling Addison's disease, results. Pigmentation of the skin, particularly of the face, is not infrequently seen in the terminal stage of glomerulonephritis and may complicate the diagnostic problem. Therapy is necessarily directed at replacement of lost salt and water. Isotonic saline must be given together with additional sodium chloride by

mouth in quantities guided by the amount of water and salt lost each day. Desoxycorticosterone and cortical extracts are of no value.¹¹

Cation Loss and Acidosis—On the other hand, sodium sparing devices may be badly damaged. The ammonia-forming ability of the tubular cells is lost and the tubule appears to lose its capacity to control urinary pH in such a fashion as to conserve base through the manipulation of urinary buffers. The excess loss of base inevitably leads to

TABLE 3 —INTRAVENOUS FLUID THERAPY IN CHRONIC DIFFUSE GLOMERULONEPHRITIS

	Dose	Comments
1 Sodium chloride 0.85 per cent solution	500-1000 cc. per day	Contains chloride ion in excess of plasma hence if used alone may increase acidosis.
2. Glucose 5 per cent	500-1000 cc. per day	No evidence that it improves renal function in man provides needed food and water, however
3 Gluco-saline (mixture of (1) and (2) equal parts)	500-3000 cc. per day	Fluid of choice for repairing dehydration. Contains chloride in approximately correct proportion, but (4) or (5) must be added to repair sodium defect.
4 Sodium lactate Ringier's solution (1 M)		Add ampule (40 cc.) to 200 cc. of (3) for $\frac{1}{4}$ molar solution—isotonic. Administer 200-300 cc. of 1 M solution diluted properly, and sufficient addition of fluid to correct dehydration as first dose, when CO_2 combining power is less than 30 vol. per cent. Adjust succeeding therapy by effect as shown by clinical and chemical response
5 Sodium bicarbonate		Ampule (1.5 gm. per 20 cc.) diluted to 100 cc. for intravenous use. Give 15-25 gm. diluted properly, intravenously as initial dose and thereafter according to effect. Oral 10-30 gm. per day
6 Total volume		Depends on state of circulation and fluid needs. Daily requirements may be estimated grossly by urine flow which should be maintained at 1000 cc. per day. Care should be taken to avoid overhydration

acidosis if replacement is inadequate. The grave import of acidosis arises not so much from the effects of a lowered pH of the body fluids as it does from the fact that acidosis nearly always bespeaks a serious imbalance of solutes with marked dehydration. The use of the alkalinizing agents listed in Table 3 may be very effective in correcting the chemical and clinical manifestations of acidosis. Nonetheless, treatment must be conducted cautiously. The patients are no longer capable of normal equilibratory responses. The physiological pattern is

brittle and inelastic and overtreatment may be as dangerous as neglect. For this reason, the doses of sodium lactate-Ringer's solution and of sodium bicarbonate are considerably smaller than those conventionally advocated. Proper hydration and careful correction of chemical imbalances must be guided by close observation of the effects. Once they are corrected, the problem of therapy does not end, since the patient's life is one of teetering along a narrow path beset on one hand by acidosis and dehydration and on the other by alkalosis, edema and, perhaps, cardiac decompensation.

The course of H₂B, charted in Figure 171, illustrates the effects and hazards of the chemotherapy of acidosis.

This white male of 24 years was admitted to the Evans Memorial complaining of nausea, vomiting, and "shortness of breath" of sudden onset and short duration. He was emaciated, dehydrated and markedly hyperpneic. Investigation revealed fixation of the urinary specific gravity at 1.010, nitrogen retention, and a striking reduction in the carbon dioxide combining power. The blood pressure was slightly elevated, but the cardiovascular system was otherwise normal. There was no history of previous renal disease. Since he was conscious, well-oriented and cooperative, fluids and sodium bicarbonate (12 gm daily) could be given by mouth. Sodium lactate-Ringer's solution (160 cc of one molar solution) was given immediately by vein in 2000 cc of gluco-saline solution. The effect of this regimen was dramatic, both from a clinical and a chemical standpoint. In three days the carbon dioxide combining power had mounted to 26 from 4 volumes per cent. The respiratory pattern reverted to normal and the plasma nonprotein nitrogen fell. Following these changes (due in part, undoubtedly, to hydration) improvement in the chemical pattern of the blood slowed. However, the patient continued to improve clinically and five days after admission he was sitting up in bed, in good spirits, and feeling well. Nonetheless, the carbon dioxide combining power remained at 30 volumes per cent and the nonprotein nitrogen at 63 mg per 100 cc. Continued therapy resulted in moderate pitting edema of the extremities, probably as a result of salt and water retention by the damaged kidneys, and little further change in bicarbonate ion occurred. The dose of sodium bicarbonate was reduced (6 gm daily) and equilibration apparently having been achieved, he was discharged on an alkaline ash diet and sodium bicarbonate. It was thought that the slight edema that remained would act to buffer the tendency to dehydration and acidosis. He remained well on this regimen and returned again to the hospital in acidosis and hypocalcemic tetany only after a lapse from regularity.

The excellent effect of alkalization and hydration is obvious in this case, but the fact that return to the normal state was impossible should be stressed. Therapy must be directed at achieving an optimal clinical response. No single criterion and no perfect clinical pattern can be set up as a satisfactory and safe gauge of therapy. Insistence on one or the other may be fatal. In this case, a vigorous attempt to return the carbon dioxide combining power to normal would have resulted in massive edema.

In addition to the oral replacement of base, dietary restriction of acid ions may be helpful in preventing acidosis. Moreover, the water

which acid ions would otherwise require for excretion is spared to the body. A sample alkaline ash diet is outlined in Table 4

Fig 171.—The treatment of acidosis in the terminal stage of chronic diffuse glomerulonephritis. H. B., a 29 year old white male, was admitted complaining of nausea, vomiting and respiratory difficulty. Renal function was markedly impaired G.F.R., 197 cc. and R.P.F., 1313 cc. The severe acidosis was treated by intravenous fluid and alkalinizing measures on admission. Thereafter water was forced by mouth and sodium bicarbonate was administered. The carbon dioxide combining power rose, but failure of the kidney to regulate the electrolyte pattern and the volume of body water resulted in peripheral edema. This required reduction of the intake of sodium bicarbonate. Discharged markedly improved on an alkaline ash diet and sodium bicarbonate. He remained, however in uremia.

Anion Retention

The retention of anions contributes to the development of acidosis in two ways, first, by increasing the concentration of acid ions, and second by stimulating water and base loss. Among the ions retained, chloride and phosphate are the most important. Chloride, in general,

follows the sodium ion, although occasionally preferential retention of this ion does occur. Leutscher and Blackman⁷ have reported such an instance following severe renal damage by sulfonamide. This situation may occur in the course of chronic diffuse glomerulonephritis, particularly in severe dehydration. Hydration, preferably with 5 per cent glucose, and alkalinizing measures, if acidosis is present, are indicated.

Phosphate retention leads ultimately to hypocalcemia as a result of the reciprocal relation between the calcium and phosphorus ionic con-

TABLE 4—DIET IN ACIDOSIS

Sample Form

Diet for M_____

It is necessary for you to avoid acid-forming foods because damaged kidneys are unable to cope with excess acid. Since most meats are highly acid-forming, it will be necessary to replace animal protein with plant protein in your diet. The following diet is a sample diet for one day. Listed below the menu you will find foods you should not eat together with those you may use as substitutes.

Breakfast	Fruit	1 serving
	Toast	1 slice with butter
	Egg	1
	Milk	1 glass
Luncheon	Cheese (cottage)	3 tablespoons, or
	Lean beef	1 medium serving
	Orange	1
	Potatoes	1 (or other vegetable)
	Bread	1 slice with butter
	Baked apple	1 with cream
	Coffee	As desired with cream and sugar
Dinner	Baked lima beans (main dish)	1 serving
	Carrots	1 large serving
	Lettuce	1 large serving
	Bread	1 slice with butter
	Milk or coffee	
	Fruit	1 serving

Drink at least eight glasses of water each day

Avoid Pork, beef, chicken, duck, veal

Eat sparingly of Seafood, lamb, cereals

You may substitute for the above Beans—lima, etc., milk, cheese, eggs

centrations. Calcium is lost in the stool and is precipitated from the blood into soft tissues. Hypocalcemia and acidosis result in a mobilization and loss of calcium from bone and may stimulate the secretion of parathormone. Syndromes resembling rickets and osteomalacia arise from the complex of factors at work. Tetany, muscular twitching and cramps may also appear when hypocalcemia is marked. Difficult and sometimes insoluble therapeutic problems are met.

The bony changes of severe and prolonged renal insufficiency do not respond readily to therapy. The process may be halted by correc-

tion of acidosis and hyperphosphatemia, but, unfortunately, permanent damage and interference with normal growth may occur before a diagnosis is made and therapy instituted. An alkaline ash diet, high calcium intake (e.g., calcium gluconate—4 gm four times a day), and increased vitamin ingestion are usually helpful. Liu and Chu⁸ have found that dihydrotachysterol (AT 10)—3 cc daily by mouth—may exert a favorable influence. It is a matter of general experience that vitamin D is valueless in improving calcium absorption in these cases. Often it is impossible to reverse the acidosis completely and one must be satisfied with retarding the pathological process.

Since hyperphosphatemia is a common denominator in all these conditions, it seems reasonable to suppose that increasing the phosphorus excretion would be of value. That this is so is illustrated by the response of H. B. (Fig. 172) to treatment with aluminum hydroxide. This substance (Amphojel—20 cc daily, Creamalin—12 tablets daily) precipitates phosphates as insoluble salts in the intestine.⁴ Since phosphate passes from the blood into the gut in the intestinal secretions, augmented excretion by this route results and ultimately a reduction in the blood level with a reciprocal increase in the calcium level occurs. Iron salts (e.g., Feosol—1 gm. four times a day) also have this action.⁸

H. B. was admitted several months after the admission described above. He confessed to dietary indiscretions and he had failed to continue his medication. He was complaining of "shaking" muscular cramps and diarrhea. Evidence of tetany was demonstrable in positive Chvostek and Trousseau signs and in fibrillary muscular twitching. It was noted that the peripheral arteries were calcified. Chemical studies (Fig. 172) revealed hypocalcemia and hyperphosphatemia in addition to a depressed carbon dioxide combining power and azotemia. He was placed on sodium bicarbonate and increased water intake by mouth. There was little change during the following four days. Amphojel was then substituted for the sodium bicarbonate. After three days the plasma phosphate had fallen from 6.2 mg to 4.25 mg per 100 cc. Cessation of the aluminum hydroxide therapy was followed by a rise of phosphorus to a level however considerably below the admission concentration. From this point improvement was progressive, the calcium concentration increasing with alleviation of the symptoms of tetany. The carbon dioxide combining power and nonprotein nitrogen content both changed toward normal levels.

Although in this instance, Amphojel was instrumental in correcting to some extent, a hyperphosphatemia the effects of concomitant measures must not be overlooked. Certainly the reestablishment of a more nearly normal water balance and of other electrolyte concentrations all played interdependent roles in producing satisfactory effects.

Cation Retention.—The retention of cations is unusual. However, increased intake may be associated with retention, as in the case of sodium in H. B. noted above. The kidney is fixed in its function to a narrow range of activity and any change from the normal cannot be adequately compensated. Rarely in far advanced renal failure potas-

sium may accumulate to the point of toxicity⁹ Reduction of intake, insulin and calcium therapy may be of value here

Anemia—A hemorrhagic diathesis often becomes apparent during the stage of renal insufficiency, the cause of which is obscure There

Fig 172—Therapeutic correction of hyperphosphatemia and hypocalcemia in the terminal stage of chronic diffuse glomerulonephritis H B., readmitted complaining of diarrhea and "shaking" Signs of tetany were demonstrated A course of aluminum hydroxide (Amphojel) resulted in marked reduction of plasma phosphate and was followed by gradual restitution of plasma calcium to a normal level Other measures employed in this case included restoration of lost fluid and base

may be bleeding from any mucosal surface—the mouth, stomach, gut, rectum, or the genitourinary tract Thus, blood loss may be a cause of severe secondary anemia, but, as a rule, such an anemia develops at this stage of chronic diffuse glomerulonephritis, and often earlier, for un-

known reasons. It is very difficult to treat, responding poorly or not at all to iron therapy. Repeated transfusions are often the only means by which one can produce even temporary relief.

CONCLUSIONS

These remarks express, for the most part, tentative opinions. The physiological changes in the course of chronic diffuse glomerulonephritis are not fully explored and understood. Therapy is often ineffective and one must often fall back upon empiricism. Unfortunately, empiricism is doubly dangerous because the variability of the course may give virtue to procedures that do not deserve it, and because meddling interference with a system so intricate as the complex of mechanisms that regulate the composition and volume of the body water must be dangerous. Therapy is therefore to be conducted as cautiously and as understandingly as possible.

THE MANAGEMENT OF SOME COMMON DISTURBANCES OF THE FEMALE BLADDER FUNCTION

SAMUEL N VOSE, M D , F A C S *

A CONSIDERABLE proportion of the women coming under the care of the urologist do so because of a disturbance of the bladder function with frequency of urination, nocturia, painful voiding, tenesmus and/or various degrees of urinary incontinence as the outstanding symptoms. Often associated with these symptoms is pain in the suprapubic area and the groins or in the lower abdominal quadrants. The frequency with which these cases appear and the usual long history of the complaint with the story of a variety of treatments at the hands of several doctors indicate that this group of cases offers a definite problem to the general practitioner as well as to the urologist. Although in numerous cases these symptoms indicate the presence of *some serious surgical* condition and demand thorough urological investigation in order to establish a diagnosis and indicate treatment, in the majority of instances they are due to local conditions in the bladder or urethra which cause pain and suffering out of all proportion to the seriousness of the pathologic involvement and are amenable to comparatively simple methods of diagnosis and treatment available to any practitioner.

Among the conditions most commonly seen as causes for this group of symptoms and which will be taken up in some detail are

- 1 Acute uncomplicated nonspecific bladder infections
- 2 Interstitial cystitis (Hunner ulcer)
- 3 Chronic nonsuppurative urethritis and trigonitis
- 4 Fibrous bladder neck obstruction
- 5 Gynecologic conditions

With the exception of the first named, all these conditions in their original state are characterized by a *clear urine*, a fact which is of great value in differentiating this group from other more serious diseases which may present the same initial symptoms. This differentiation will be helped, also, by the observance of a few fundamental urologic principles of extreme importance.

IMPORTANT UROLOGIC PRINCIPLES

- 1 The presence of blood in the urine demands immediate and thorough urological investigation
- 2 Resistant, chronic or recurrent urinary infections usually indicate the presence of some complicating lesion, often obstructive, which

* Professor of Genitourinary Surgery, Boston University School of Medicine, Surgeon-in-Chief, Genitourinary Department, Massachusetts Memorial Hospitals, Boston

must be removed in order to produce a cure. Chronic cystitis is usually a symptom and not a disease

3 The failure of simple treatment to bring about a cure of any of the conditions to be discussed indicates an error in diagnosis or complications that require further diagnostic measures

With these principles in mind and without recourse to extensive urologic procedures, the general practitioner may safely diagnose and treat the majority of these cases

OUTLINE OF INVESTIGATION

The *history* is of great importance. Precise information should be obtained as to the frequency of urination, nocturia, the relation of the discomfort to the act of micturition, whether before, during or at the end, the amount passed at each urination, circumstances which aggravate the symptoms, pain in other parts of the body which may accompany voiding, dysuria, and urging or incontinence. The circumstances under which the initial symptoms occurred may be of significance. The patient's theory as to the cause is often of interest and may be of value in diagnosis. The *general history* should pay particular attention to age, menstrual history, antecedent infections, urinary or otherwise, marital status, childbirth, or other trauma, chronic fatigue, and any symptoms suggesting endocrine disturbances. A *general physical examination* is, of course, essential to any diagnosis

Special Examination of the Genitourinary Organs.—Thus should include the following in most cases

- 1 Palpation of the kidneys and ureteral areas
- 2 Inspection of external genitalia.
- 3 Bimanual pelvic examination and inspection of cervix by speculum.
- 4 Obtaining catheterized specimen of urine for microscopic examination and culture
- 5 Overdistention of the bladder to reproduce pain of interstitial cystitis.
- 6 Calibration of the urethra

The local examination is best carried out shortly after the patient has voided. There is always sufficient urine left in the bladder to obtain a specimen for culture and microscopic examination, and the passage of the catheter after voiding will reveal the presence of a significant residuum. On inspection of the external genitalia, one notes the condition of the perineum, the presence of a cystocele or rectocele, evidence of infection in Skene's glands, the state of the urethral meatus, particularly as to caruncle, and, in cases of incontinence, one should search for an ectopic ureteral orifice or vesicovaginal fistula. The urethra and base of the bladder are palpated vaginally with particular attention to tenderness and thickening. A soft rubber catheter is passed after thorough cleansing of the vulva with soap and water

A culture should be made from urine obtained at the *first catheterization*, otherwise contamination must be considered as a probability. The specimen is examined chemically and microscopically. Following this, if the urine is *clear and free from pus or blood* 1 ounce of 1 per cent novocaine should be instilled into the bladder and allowed to remain five minutes. It is then withdrawn through a catheter and the bladder is distended to the point of tolerance with sterile water or boric solution, noting character and location of pain caused by overdistention. The fluid is then allowed to run out and the last few cubic centimeters are watched carefully for traces of blood. Such bleeding is highly suggestive of interstitial cystitis, and if the history points to this condition and no blood appears on the first overdistention, the maneuver should be repeated.

The urethra may be calibrated by a metal sound or bulbous bougie. The normal female urethra will easily admit a 26 F sound with little discomfort. A small caliber usually indicates a granular urethritis or stricture.

If the catheterized specimen contains pus, the above instrumental manipulations should be omitted and the infection treated as later outlined.

Completion of such an examination will furnish the data essential to a working diagnosis. Details of the diagnostic points will be included in the discussion of the several conditions to be considered.

ACUTE CYSTITIS

Infection of the female bladder is extremely common. While this condition is often an acute flare-up of a chronic process in other parts of the urinary tract, such as pyelonephritis, a goodly number of cases are uncomplicated, acute conditions which are usually self-limited, but which respond more rapidly if proper treatment is administered early.

Etiology—The shortness of the female urethra is a factor in the frequency of this condition, infection ascending from the vestibule in the wake of trauma of some sort such as that resulting from holding the urine too long after the desire to void occurs. "Honeymoon cystitis" if of similar etiology, as are certain cases of postoperative cystitis. Exposure to cold, chronic fatigue or irritating food or drinks may predispose to such infections. Many cases follow acute upper respiratory infections, and immobilization in bed for minor ills such as fracture of the ankle is often accompanied by cystitis. By far the most common organism is some strain of *Bacillus coli*. *Streptococci* and *staphylococci* are frequently found and particularly resistant infections may result from *Streptococcus faecalis* and *Bacillus proteus*. Infections caused by the last named are practically always due to organisms introduced by instrumentation. Since the choice of a therapeutic agent may be influenced to a considerable extent by the staining qualities of

the infecting organism, its identification by smear or culture as early as possible is desirable.

Diagnosis—The symptoms of acute cystitis are quite distinctive, well known and easily recognized. The sudden onset of frequency of urination, urging and tenesmus, with pain on voiding, points unmistakably to a bladder infection. The question is whether the infection is a simple, uncomplicated process or whether it is a manifestation of or accompanied by other more serious conditions. Often this cannot be decided early. A history of previous similar attacks suggests the presence of complications or latent upper urinary tract infection.

Bleeding is a common occurrence in acute cystitis. It usually follows by a few hours the onset of other symptoms and is comparatively small in amounts and of short duration, although clots may be present. It is apt to be terminal in character although the female patient is often unaware of this. Dull pain in the loin due to edema of the bladder mucosa may be present, although it usually is not as severe as that of acute pyelonephritis or ureteral obstruction. Constitutional symptoms are mild the temperature rarely exceeding 100° F, and chills are practically never seen. A dull headache and slight malaise are often present.

On physical examination there is rarely any loin or costovertebral tenderness but tenderness in the suprapubic area and soreness in the bladder on bimanual pelvic examination may be found. The catheterized specimen shows varying amounts of pus, and blood cells if the infection is of the hemorrhagic type. The urine should be tested carefully for sugar, as diabetes is an important predisposing factor in many urinary infections. The red or white blood count rarely shows any change due to the infection, but may reveal conditions important in its etiology.

Certain cases of acute gonorrheal infection of the urethra may be mistaken for acute nonspecific cystitis, particularly if the history of exposure is withheld. In this condition pain on voiding is the outstanding symptom, rather than frequency, and the presence of discharge and redness of the urethral meatus should lead to the taking of a smear and culture which will determine the diagnosis.

Treatment of Bladder Infection—The treatment of acute cystitis consists of (1) general supportive measures, (2) relief of pain or discomfort, (3) specific drug therapy and (4) local treatment.

1 **GENERAL SUPPORTIVE MEASURES**—During the acute stage the advisability of bed rest depends on the severity of the constitutional symptoms. If these are mild, ambulatory treatment is permissible. Fluid intake should exceed 2000 cc. Many patients limit fluid in an effort to reduce the frequency of urination. This usually defeats its own purpose. Stimulants and irritating foods should be avoided, but otherwise a full diet may be allowed.

2 **MEASURES TO PROMOTE COMFORT**—Occasionally, the pain of cystitis is so severe that morphine may be necessary. Usually, however,

tablets of aspirin, 5 grains, and codeine sulfate, $\frac{1}{2}$ grain by mouth at intervals of four to six hours, will suffice to relieve the discomfort. Heat applied to the pelvic area by electric pad or hot water bag is very helpful. Perhaps the greatest degree of comfort can be obtained from the hot sitz bath. This should last from fifteen to twenty minutes as the temperature of the water is gradually raised to 115° F. A hot prolonged vaginal douche of saline may be substituted for the sitz bath.

3 SPECIFIC DRUG THERAPY—During the past few years, drugs of the sulfa group have largely replaced other agents in the treatment of urinary infections. They are particularly effective in most cases of acute cystitis, as kidney function is not affected and patients are usually able to tolerate the drug in sufficient dosage to control the infection. Clinical experience as well as *in vitro* experiments have shown that high blood concentrations are not necessary and that a urine concentration of 10 mg per 100 cc is bacteriostatic to most of the organisms found in acute bladder infections. A dosage of 0.5 gm three times a day is sufficient to maintain such a level in most instances. There is little choice between sulfathiazole, sulfadiazine and sulfamerazine in this group of cases. The urine should be rendered alkaline by the administration of sodium bicarbonate 10 grains three times a day, and care should be taken to see that anything that might contribute to dehydration is not allowed to occur. *Penicillin* has been disappointing in urinary infection. The most common organism, *Bacillus coli*, is affected only in high concentrations and only to a limited extent. In infections due to gram-positive organisms penicillin is of more value.

For those cases in which the sulfa drugs are not tolerated or are ineffective, a wide choice of other agents is available. *Caprokol* in 0.10 gm capsules administered three times a day has a soothing effect in urinary infections and is bacteriostatic to a variety of organisms. It should be given only after food, and sodium bicarbonate interferes with its action. Fluids should be limited to 1000 cc daily when giving this drug. *Calcium mandelate* is the best form of mandelic acid for routine use. Resistant *Streptococcus faecalis* infections are favorably affected in some cases by this drug. It should be given in dosage of 12 gm daily in four divided doses of 3 gm each. Again, fluids must be limited to 1000 cc daily, thus depriving the patient of the benefit of a large fluid intake so desirable in the treatment of acute infections.

4 LOCAL TREATMENT—In general, *extensive instrumentation* is undesirable in acute infections of the urinary tract. In acute bladder infections in the female, however, there is no danger in gently passing a small size, soft rubber catheter. This provides a specimen for bacteriologic study and rules out such conditions as residual urine or urethral obstruction. Following the collection of the specimen, which should consist of the *last* drops of urine rather than the *first*, 1 ounce of 10 per cent argyrol should be instilled into the bladder and allowed to remain.

as long as tolerated. Improvement following this simple procedure is often dramatic.

In many cases with severe symptoms, great relief may be afforded by *constant catheter drainage*, with frequent irrigations using an 0.8 per cent sulfanilamide solution. A closed irrigation and drainage system gives the best results. The catheter is connected to a glass Y tube, one arm of which leads to the drainage tube and bottle while the other arm is connected to the tube from a reservoir containing the irrigating solution. At suitable intervals (every two or three hours) the reservoir tube is unclamped and about 50 cc. of the solution is allowed to run into the bladder, the drainage tube being closed temporarily by pinching with the thumb and finger. Never put the clamp on the drainage tube. Drainage should be maintained for several days.

The usual course of acute cystitis is from four to ten days. If infections persist beyond this time, complications should be suspected and further urological investigation carried out. Apparent recovery should be confirmed by negative smears or cultures at intervals for several weeks.

CHRONIC INTERSTITIAL CYSTITIS (HUNNER'S ULCER)

This condition is undoubtedly one of the most distressing maladies affecting the urinary bladder. One reason for this is that it is frequently overlooked owing to the fact that *the urine usually shows no changes*. Furthermore, cystoscopy may fail to reveal the typical bladder changes unless one is alert to find them, hence the name, "elusive ulcer." Formerly considered an uncommon condition, it is now recognized as the cause of many cases of long-standing bladder trouble in which various methods of treatment, often including abdominal surgery, have been tried over many years without relief. It is an inflammatory process involving all layers of the bladder wall, particularly the submucous and muscular coats. The mucosa may show definite small ulcerations or areas of hyperemia which bleed on overdistention of the bladder. The muscular coats are thickened and show marked lymphocytic infiltration.

Etiology—The etiology is obscure, and many theories, including that of focal infection, have been advanced. Recently hormonal influences have been mentioned as possible factors. For some years this theory has seemed to the author to be a logical explanation of the occurrence and characteristics of this disease. It is very rare in the male, and in the female the majority of cases occur at or after the menopause. In a series of cases observed by the author in which the condition occurred in women below the menopausal age, the victims, almost without exception, gave a history of radical pelvic surgery, involuntary sterility, dysmenorrhea or other evidences of impaired ovarian or other endo-

crine function Cancer of the bladder is extremely uncommon in the presence of this condition

Diagnosis—The characteristic symptoms of interstitial cystitis are *marked frequency of urination* and *pain* This pain is often relieved by emptying the bladder but sometimes it is continuous regardless of the state of distention of the bladder It occurs usually in the suprapubic area and is excruciating if the bladder becomes the least bit overdistended Bizarre types of pain in various parts of the body may be a part of the picture. One patient had pain in the shoulder and back of the neck which was entirely relieved following treatment of the bladder Pain in the lower abdominal quadrants and occasionally in the loin may be among the complaints The *frequency* is noteworthy for its *clocklike regularity*, and often is so severe that micturition is necessary several times per hour Night frequency is as common as day frequency, a point of some value in differentiating this condition from granular urethritis and trigonitis The symptoms in some cases are affected either favorably or unfavorably by the menstrual cycle The urine is usually *clear* and *sparkling* and shows no growth on culture At intervals there may be microscopic hematuria, especially if the urine has been held for a longer period than usual

The diagnosis can often be made over the telephone A long history, often of many years' duration, of frequency and pain without changes in the urine should immediately raise the suspicion of Hunner's ulcer While cystoscopy is the only sure means of diagnosis, a tentative conclusion may be reached by observing the effect of overdistention of the bladder After the vulva has been cleansed with soap and water a soft rubber catheter is inserted into the bladder and a specimen of urine obtained If this is clear microscopically, 1 ounce of 1 per cent novocaine solution is instilled and allowed to remain in the bladder for five minutes It is then withdrawn and the bladder is distended to the point of discomfort with boric solution or sterile water The fluid is then allowed to run out and the capacity of the bladder measured This is sometimes as much as 300 cc, but usually does not exceed 180 to 240 cc (6 to 8 ounces) The presence of blood in the last few drops of fluid is strong presumptive evidence of the presence of interstitial cystitis If the first distention does not produce bleeding, it should be repeated

Treatment—While *electrocoagulation* through the cystoscope under anesthesia is perhaps the most reliable form of treatment, its effects are not permanent nor is it universally successful even as a palliative measure Relief may be obtained in many cases from *general measures* and simple local treatment. Elimination of irritating items from the diet, rest, correction of focal infections and the liberal use of phenobarbital in nervous patients are among the valuable measures to be advised In spite of the evidence of endocrine influences in the etiology of this disease, my experience with *hormonal therapy* has been disap-

pointing Individual cases have shown temporary improvement from the administration of various estrogens, adrenal cortical hormone or testosterone, but there has been no uniformity in results Much further clinical trial is necessary before hormonal treatment can be recommended for general use.

Local treatment, which has yielded the best results in my experience, consists in the instillation into the bladder of silver nitrate solution in increasing concentration. Treatments may be given as often as three times a week, although results often are as good if the interval is a full week. The bladder is emptied with a soft rubber catheter and 1 ounce of 1 per cent novocaine solution is instilled and allowed to remain five minutes This is withdrawn and an ounce of silver nitrate solution is instilled and retained as long as tolerated A 1:2000 solution is used at first and the strength gradually increased as tolerated, eventually reaching 1 per cent. Improvement is usually gradual but sometimes dramatic If marked relief is not produced within a few weeks the diagnosis should be questioned and further urologic investigation undertaken Tuberculosis of the bladder may produce symptoms similar to those of interstitial cystitis, but there is usually pus in the urine. Symptoms are aggravated by silver nitrate. In doubtful cases, tuberculosis should be ruled out by guinea pig inoculation In extremely severe cases relief may be obtained by diversion of the urinary stream by uretero-intestinal anastomosis

CHRONIC GRANULAR URETHRITIS AND TRIGONITIS

This condition often accompanies interstitial cystitis, and perhaps may be a forerunner of fibrous bladder neck obstruction, to be discussed later, but for purposes of classification it will be considered as that group of cases which show *granular, nonsuppurative* inflammation of the posterior third of the urethra and trigone, with or without polypoid changes at the sphincteric margin, but *without urinary obstruction*

Etiology—Many theories are held as to etiology Focal infection, particularly *chronic* cervicitis, often accompanies it. Previous specific or other suppurative types of infection may precede it. Tissue changes include congestion and thickening of the entire urethra, and some observers have reported infection of submucosal glands Polypoid changes of various degrees may occur at the bladder neck. Seen cystoscopically, the trigone and proximal urethra, both of which are of similar embryological development, show a diffuse granular inflammation, often accompanied by a pseudomembrane occupying part or all of the trigone

Diagnosis—The symptoms are *frequency* of urination and less commonly, *burning on urination* Discomfort in the suprapubic regions and groins may be present, but less severe than that due to interstitial cystitis The frequency is less marked at night and may be relieved by lying down. *Urgency* and *slight incontinence* are common

The disease is most frequently seen in the middle years, but has been reported in young girls. Again, the symptoms may be affected by the onset of the menstrual period.

Examination may reveal tenderness in the urethra on palpation and on passage of the catheter. There is no obstruction and no residual urine. Culture may reveal organisms but there is *rarely pus in the urine*. Passage of a sound may give the impression of a "snug urethra."

The tentative diagnosis rests on the day frequency, the tender urethra, the clear urine and the absence of pain on distention. Temporary relief of symptoms by the single passage of a sound often occurs and is of great diagnostic value.

Treatment—*General measures* include clearing up of focal infections, such as cervicitis, in addition to dietotherapy and chemotherapy as previously outlined if infection is present. The one local measure of great value is *gradual dilation of the urethra* with metal sounds or dilators. The procedure is less painful if one of the anesthetic jellies is applied via a cotton swab before passing the sound. Treatments should be given at weekly intervals starting with 24 F or 26 F and increasing the size as tolerated. It is important to *overdilate* the urethra, and numerous cases which have seemed resistant have responded to dilation up to 31 F or even 33 F. Instillations of silver nitrate in conjunction with the dilations as recommended for interstitial cystitis are of value.

FIBROUS BLADDER NECK OBSTRUCTION

Although, as previously stated, this condition may represent the end result of granular urethritis, it presents a distinct clinical entity inasmuch as some measure of *urinary retention* is usually present. The clinical picture is very similar to that of prostatic obstruction of the fibrous type in the male and the term "female prostate" is quite appropriate. Some observers have found tissue from the bladder neck in the female that closely resembles prostatic tissue. Whether the tissue changes are actually due to glandular hypertrophy or fibrous tissue contracture is not pertinent to the present discussion, as the *presence of obstruction*, whatever may be its nature, is the cause of the symptoms and the secondary changes, which include bladder trabeculation, infection and renal insufficiency, exactly as in prostatic obstruction.

Diagnosis—The condition is seen most frequently in the older age group although it may appear at any age. In the early stages the principal symptoms are *urinary frequency* and difficulty in emptying the bladder. Secondary infection is common and aggravates the frequency. Hematuria is not uncommon, but if present it should not be assumed to be due to this condition. Constitutional symptoms, even to various degrees of uremia, may be the first reason for seeking medical care.

On examination, the bladder may be palpable suprapubically. Obstruction to the small catheter is not necessarily present, but *some*

residual urine is the rule Examination of the urine shows little unless complicating infection is present The blood nonprotein nitrogen is often elevated

Treatment—The correction of this condition depends on the establishment of adequate drainage Often *constant catheter drainage* is necessary as described under the treatment of acute cystitis Dilation of the urethra by sounds may suffice Size 28 F is adequate Secondary infection should be treated by chemotherapy and any uremia by copious intravenous fluids, 5 per cent glucose in saline being the most effective If complete relief of symptoms and elimination of residual urine are not secured by these measures, *transurethral resection of the bladder neck* may be expected to afford complete relief in most cases

GYNECOLOGIC CONDITIONS

Although a complete discussion of all the gynecologic conditions that may cause urinary symptoms is beyond the scope of this paper, several general observations are pertinent The most important is that essential urinary pathologic change may accompany the pelvic disease and actually be *responsible for the urinary symptoms* The results of pelvic surgery may thus be disappointing For instance, frequency of urination is commonly seen as a symptom of cystocele or prolapsus, but bladder neck obstruction also occurs very frequently in conjunction with cystocele and should be searched for in such cases *Pus in the urine* is rarely cured by gynecologic operations and we have recently seen one case in which repair of a cystocele was done on account of urinary symptoms due to renal tuberculosis Urethral caruncle is often accompanied by changes of a similar nature in the proximal urethra In general, the cause of urinary symptoms should be sought in the urinary tract, before assuming that such symptoms will be relieved by correction of gynecologic conditions

MANAGEMENT OF THE MEDICAL CONVALESCENT

ROBERT W WILKINS, M D *

THE successful management of the convalescent patient requires the utmost in both the art and the science of medicine. It necessitates a practical blending of patience, imagination, tact, humor, sympathy and encouragement with the scientific use of therapeutic agents, often over long periods of time. It demands that the physician give attention equally to the physical and to the *emotional* debility produced by disease. For with the weakening of the body during illness there comes an even greater weakening of the will, and with the lowering of physical reserves there is an even more deplorable loss of emotional maturity, that, without question, is the greatest single cause of the perpetuation of invalidism. It is the purpose of this paper to describe some of the lessons learned during the care, both in the hospital and in the home, of convalescent patients who have suffered major medical illnesses.

1 Convalescence Requires Time—The period of convalescence demands the time not only of the patient but also of the doctor. No other single therapeutic measure is so valuable to or so valued by the patient as the devotion of an adequate amount of time by his physician. It not only allows the doctor to gain full knowledge of the patient and the effects of his illness, but also permits the patient to discover under the encouragement and guidance of his physician the relative importance of the physical and the emotional aspects of his disease. Thus the physician, himself, as psychiatrists are continually pointing out, becomes a potent therapeutic agent, capable of shortening the total convalescent period and thus eventually saving both himself and his patient much time.

The convalescent patient deserves, in fact, he must have, full opportunity to bring out his complaints, questions, fears and fancies in private conversation with his doctor. The actual interview may be greatly facilitated and shortened by the patient's jotting down during the day anything he may wish to discuss. During the talk he should be encouraged to speak frankly of his troubles—physical, mental and emotional. The psychotherapeutic value of such "mental catharsis" cannot be overemphasized. The attitude of the doctor during the interview should be one of sincere, calm, unhurried and uncriticizing interest.

From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston

* Associate Professor of Medicine, Boston University School of Medicine, Physician, Massachusetts Memorial Hospitals, Member, Evans Memorial, Massachusetts Memorial Hospitals

He should inquire after the common complaints, such as headache, backache, insomnia, mental depression, weakness, fatigability, constipation and dysuria, and should attend to any bizarre or vague symptoms that the patient may describe. Such disturbances may be more distressing than those arising from serious pathologic processes and very often they can be relieved by simple remedies, or merely by reassurance or encouragement.

Every physician must discipline himself against slipping into a superficial, breezy or hurried relationship with his patients. During his visits he must steel himself to devote the time necessary for a satisfying discussion. He should come unattended by a coterie of followers, and should settle himself comfortably in a chair, with a manner of complete absorption in the patient and his problems. Incidentally, by so doing, he can give the appearance of spending more time than he actually does. But at best, considerable time must be allotted to this procedure.

2 **Convalescence Should Start Early**—As a matter of fact, convalescence should start with the first visit of the doctor. It should begin merely in a psychological sense, by placing great emphasis on getting well. The physician should speak optimistically of recovery, he should mention his purpose to build up resistance, restore strength, relieve pain and promote activity, even when these objectives may be relatively remote. But in addition, as soon as possible, the convalescence should be physical. Much, perhaps too much, has been written lately about the evils of bed rest. Obviously, physical rest is necessary for the seriously ill patient. But it should be interrupted just as soon and as often as does not actually harm the patient. This is especially true in the case of elderly and of cardiac patients. The dangers of pulmonary complications, particularly hypostatic pneumonia and pulmonary infarction, are minimized by early ambulation. Constipation, dysuria, decubitus ulcer, postural hypotension and muscular and skeletal weakening are avoided by abandoning complete bed rest. But more important even than these is the maintenance and boosting of morale, of hope and of the will to recover by an early initiation of convalescence. Neither fever, pain, cardiac decompensation, weakness nor fatigability should be accepted as absolute contraindications. Even when he cannot be gotten out of bed, the patient should be started on passive and then on active movements. He should be massaged, turned from side to side, raised and lowered in the bed, and passively exercised not only to relieve pressure points and muscular aching, but also to speed the peripheral circulation, promote pulmonary ventilation and drainage, and assist bowel and bladder evacuation. Supplemented early by active muscle tensing, later by limb flexing, and finally by coordinated exercises in bed, the patient can do much to build up his strength for getting out of bed.

3 **Convalescence Must Be Painless**—Perhaps no single symptom is so

distressing and demoralizing to the human organism as pain. It prevents rest and sleep, robs the appetite, retards digestion and elimination, promotes weakness and collapse, and destroys emotional equanimity. It must be abolished. On the other hand, every precaution should be taken to avoid the development of dependency or addiction to drugs.

Physicians are altogether too prone to continue the use of opium derivatives into the period of convalescence. Beside the dangers of addiction, they forget the undesirable side effects of morphine, especially its respiratory depressant and constipating actions. If opiates are necessary for pain, it is well to remember that, dose for dose, dilaudid is ten times as analgesic but *only four times* as depressant as morphine. Thus administered in doses of 0.0005 to 0.006 gm, or $\frac{1}{120}$ to $\frac{1}{10}$ grain (one-sixth the dose of morphine), it is more effective as a pain killer but less depressant, and incidentally less constipating. Codeine, dose for dose, is only one-sixth as analgesic and one-fourth as depressant as morphine. Hence, relative to its analgesia it produces slightly more depression than morphine. However, it is less constipating and used in doses of 0.015 to 0.06 gm, or $\frac{1}{4}$ to 1 grain (six times the dose of morphine), it is better for repeated use. Incidentally, larger doses of codeine than 0.06 gm (1 grain) have no greater analgesic effect, but do have a greater depressant effect.

Demerol, the new synthetic analgesic, is almost as potent as the opiates, and while it may lead to addiction it apparently is much less likely to do so than morphine. Also, it has little or no central nervous or respiratory depressing activity, and no bronchospastic or constipating action. It should at least be tried in substitution for or alternation with the opiates. The dose is 0.03 to 0.2 gm ($\frac{1}{2}$ to 3 grains).

Many physicians have forgotten the pharmacological fact that simple, safe analgesics, such as acetylsalicylic acid and acetphenetidin, used synergistically become effective pain killers, especially when potentiated by a sedative. For example, the following prescription is very good.

R Pentobarbital	
Acetylsalicylic acid	3
Acetphenetidin	3
Mix, make 20 capsules	3
Label: Take one or two capsules for pain	

The addition of caffeine with sodium benzoate, 5 gm, to the above prescription makes it especially good for headache. Or, the combination of aspirin and phenacetin can be brought up to the necessary analgesic action by the addition of very small doses of opiates, for example

R Acetylsalicylic acid	6
Acetphenetidin	6
Codeine	6
Mix, make 20 capsules	06
Label: Take one or two capsules for pain	

Those of us in medical practice, much more than our surgical colleagues, are prone to forget the usefulness of the local anesthetics for relieving muscular, arthritic, pleuritic or neuritic pains. Procaine hydrochloride in a 1 to 2 per cent solution, injected at the site of origin or reference may relieve intractable pains when nothing else will. Incidentally, 5 cc of a 0.1 per cent solution of procaine injected slowly intravenously is very good for generalized pruritus.

4 *Convalescence Should be Restful*—The enforced inactivity of the patient often makes true rest and relaxation difficult for him. At night sleep may be fitful and unsatisfying while during the day the hours drag wearily by. At the outset, it may be well for the physician to reassure the patient about the number of hours of sleep he should have, pointing out that seven or eight out of the twenty-four is the *most* he can expect and that if he sleeps during the day, he probably will sleep less at night. Also, the doctor can do much to help the patient arrange a daily schedule in which diversions such as books, the radio, the mail, and a moderate number of brief, cheerful visitors are interspersed with the necessary routine of resting, eating, bathing, eliminating and exercising.

The convalescent period is an excellent time to dust off a discarded hobby or to develop a new one. Nature study, stamp collecting, writing, drawing, sewing or other artistic pastimes, to mention but a few, are within the limits of most convalescent patients. Incidentally, the physician with a hobby can much more enthusiastically recommend one to his patients.

As for sedatives, they must be used with considerable thought and care. It is well for the physician to select from the host of sedative drugs a few with which he can become familiar and upon which he can rely. I have selected the barbiturates, the bromides, chloral hydrate and paraldehyde. These four are effective and relatively safe, and allow sufficient variety to avoid toxicity or habituation. By all odds, the most generally useful of the sedatives are the barbiturates. But again there are so many derivatives that I have selected two: phenobarbital and pentobarbital, for routine use.

The sedative action of all the barbiturates is essentially the same, except for the element of time. Depending on their chemical structure, which makes them more or less stable in the body, the different sedative barbiturates are more or less slowly acting. Phenobarbital, a relatively stable derivative, has a slow, long action, since it must be mainly eliminated by the kidney. Pentobarbital, on the other hand, has a quick, short action, since it is unstable and readily metabolized by the liver. Incidentally, it is well to remember that, in the presence of kidney disease, the long-acting barbiturates may accumulate, while with liver disease the short-acting may do so.

Thus, if a relatively slow, long effect is desired, for example, a 'background' of mild sedation, it may be secured with phenobarbital.

0.015 to 0.03 gm ($\frac{1}{4}$ to $\frac{1}{2}$ grain) three times a day For a quicker shorter action, as to aid sleep without leaving a hangover, pentobarbital, 0.05 to 0.2 gm ($\frac{3}{4}$ to 3 grains) is usually most helpful By a combination of the two agents in the proper dose and sequence almost any sedative effect may be produced

The bromides are milder, slower to act and longer acting than the barbiturates They are eliminated by the kidney (like the chlorides), and tend to accumulate slowly in the body The dangers of chronic bromidism with psychosis, anorexia, constipation and acneiform dermatitis may largely be avoided by alternating the bromides with another sedative at least every month

Chloral hydrate is a neglected sedative It is especially useful as an occasional hypnotic, given in a dose of 0.3 to 0.6 gm (5 to 10 grains) in hot milk, on retiring Paraldehyde is a safe sedative, and can be administered orally, intramuscularly or, with caution, intravenously Its only undesirable characteristics are its odor and its tendency to irritate the lung, where it is largely eliminated The dose is 4 to 10 cc (1 to $2\frac{1}{2}$ drachms) and it does not require sterilizing when given parenterally

Again I wish to emphasize the sedative effects of reassurance and encouragement of the patient Very frequently he feels misunderstood and unappreciated and fears or resents that the family regard him as a burden and do not recognize his efforts to get well It is advisable to call in the family and explain this situation to them and at the same time to point out to the patient the tendency for the convalescent to develop an infantile craving for sympathy and attention By thus frankly dealing with the patient's fears and resentments, they may be relieved and allow him to relax and rest

5 During Convalescence Bodily Functions Must Be Regulated Towards Normal—Most Americans are preoccupied anyway with their bowels and especially so when they become ill, believing that all disease is at least partially due to disturbed bowel function Therefore, for psychological, if for no other reasons, it is necessary to regulate the convalescent patient so as to have regular bowel movements At the same time it is wise to avoid the enema or the cathartic habit As soon as possible, constipating medication should be stopped, the patient should be gotten out of bed, and a diet providing bulk, but not necessarily "roughage," should be instituted Enemas should not be given oftener than every three days, and cathartics should be restricted as much as possible Instead, mineral oil, fruit, and especially adequate amounts of fluid should be used A glass of hot water flavored with sodium chloride or lemon juice may be given before breakfast, to start the desired gastrocolic reflex Patients should be reassured when they do not have daily bowel movements, but their desire to do so is usually so firmly ingrained that the physician has to acquiesce in this matter for the sake of the patient's mental and emotional equanimity

A word on the frequency of rectal impaction among elderly convalescent patients may not be amiss. A rectal examination should be done at least once during the recovery period, and if rectal fecaliths are present, retained oil enemas should be given, followed, if necessary, by digital extraction.

The avoidance of urinary retention, on the one hand, and of retrograde urinary tract infection, on the other, requires forethought. Catheterization should be reserved as a last resort, and whenever possible, patients, especially elderly males, should be allowed to get out of bed to urinate rather than run the risk of infection. If no other course is open, the use of the catheter should be preceded and followed by doses of sulfathiazole, 1 to 2 gm a day, along with forced fluids, while rigid aseptic technic is observed during the procedure.

The care of the skin is particularly important in bedridden patients. Supporting pillows and rubber rings, and frequent massages and changes of position are prophylactic. For the local treatment of decubitus ulcers, continuous wet packs of penicillin, dissolved in normal saline, 250 to 1000 units per cc, is the treatment of choice. Supplemented by 120,000 units a day of parenteral penicillin in divided doses, when there are systemic signs and symptoms, this regimen should clean up the gram-positive infections. For the gram-negative, as well as gram-positive infections, Weinstein's solution of 10 per cent urethane, 1 per cent sulfanilamide in sterile water, as a continuous wet pack is very effective. Packs should be changed every twenty-four hours and surgical débridement should be done whenever necessary.

The appetite should be stimulated if necessary, by the use of the old-fashioned bitter tonics, such as tincture of *nux vomica* and compound tincture of gentian. They may be prescribed together as follows:

℞ Tincture <i>nux vomica</i>	10
Compound tincture gentian	qs 170
Label: A teaspoonful before meals.	

Newer fashioned vitamin preparations of the B group also are valuable.

The diet, of course, must be suited to the patient, but it should not be left to his discretion. Rather, it should be prescribed definitely, preferably by list, in kind, amount and frequency. This reassures the patient and gives him an opportunity to cooperate in promoting his convalescence. At the very least, the doctor should discuss and enumerate what foods should not be eaten. In most convalescent patients, these include fried or fatty foods, pastries, animal and vegetable oils, melons, cucumbers, onions, cabbage and other "rough" or raw vegetables, spices, relishes, mustard and sauces. The diet should include added vitamins, calcium (usually as milk) and protein, as meat, eggs and milk.

6 **Convalescence Must Progress Unremittingly**—In so far as the physician is able to promote it, convalescence should progress without remission. He should gently, but firmly, insist on ever-increasing activity and independence, encouraging and reassuring the patient to avoid invalidism. In general, patients who have had serious illnesses are overcautious and overanxious. They lay great stress on their symptoms, most of which are of little or no significance. Therefore, they need to be told quite definitely and usually quite frequently which symptoms and signs are, and which are not, of any importance. In this way the development of a symptom neurosis may be avoided. Also, the physician should prescribe the amount and kind of exercise, usually insisting on gradually increasing rather than on restricting the patient's activities. It is amazing how much of this type of supportive psychotherapy the convalescent patient may need.

SUMMARY

The successful management of medical convalescence requires a great deal of time with especial attention to the details of the psychic and physical debility produced by the acute illness. Convalescence should begin early and progress unremittingly, it should be painless and restful, and should restore not only normal bodily function, but also emotional maturity and independence. Considering the relatively long duration of convalescence and the increasing number of convalescent patients in our aging population, the problem is an immense one, and anything that can be done to shorten the process is eminently worth-while.

OBESITY IN CHILDREN

NATHAN B. TALBOT, M.D.

CLINICIANS dealing with children see a great many patients who are overweight for their height. Of the children who are seen in the out-patient and in-patient departments of the Massachusetts General Hospital, approximately one in ten fall into this group.

Definition of Obesity—Though most overweight patients are obese, a careful examination sometimes shows that the extra weight is due to a well developed musculature rather than to an excessive accumulation of adipose tissue. Such muscular individuals though "overweight," do not properly come under the classification of obesity. In fact, if obesity is defined as an accumulation of subcutaneous fat which is excessive with relation to the underlying musculature and bones, then certain children may be obese without being significantly overweight for their height.¹ Generally speaking however, most persons who weigh 20 per cent or more than the normal for their height and age are obese.

CAUSES OF OBESITY

Fundamental Causes—The evidence now available clearly establishes the fact that obesity is due to an intake of calories which exceeds the caloric requirements for energy metabolism, physical activity and growth (protein anabolism).^{2, 3} Thus, in the development of adiposity the two important variables are the caloric intake and the caloric expenditure. A relative increase in the diet or a relative decrease in the energy metabolism, physical activity and/or rate of protein anabolism (growth) will tend to yield a surplus of calories which may be stored as body fat.

Most obesity is due to overeating rather than to a diminished energy expenditure on a normal dietary intake. Not uncommonly patients or their parents will cling tenaciously to the thesis that the quantity of food eaten is not large. However, when this is the case, it is almost always possible to elicit a history of dietary excess at some earlier date. In other words, once a patient has eaten too much and become fat, he will tend to remain so if he is eating a maintenance diet. He will not lose weight until such time as he eats fewer calories than he is expending.

From the Department of Pediatrics, Harvard Medical School and the Children's Medical Service, Massachusetts General Hospital, Boston. The observations and points of view recorded here were based upon studies supported by the Commonwealth Fund of New York and the Permanent Charity Fund of Boston. Assistant Professor of Pediatrics, Harvard Medical School. Assistant Physician, Massachusetts Memorial Hospital.

Contributing Causes—A number of different factors may induce overeating. Among these are personality problems,^{4, 5} organic lesions of the brain (especially of the hypothalamus)⁸ and hypoglycemia.⁸ On the other hand, physical inertia, hypometabolism and decreased protein anabolism (slow growth) may be responsible for a decrease in the energy requirements.

Of these factors, the personality ones are by far the most important in the majority of obese boys and girls. Some children tend to nibble at food to help relieve themselves of worry, unhappiness or boredom. Others have become accustomed to tables heavily laden with nutritious foods and to seeing their parents, brothers or sisters take gluttonous servings. Sometimes parents erroneously assume that a large appetite per se ensures good health and therefore urge their children to eat too much. Similarly, parents may not be aware of the normal decline in appetite which may occur at about two years of age when the rapid growth of infancy subsides. Attempts to prevent such a normal decline in appetite has led to the development of adiposity in acquiescent children. In the resistant child the same treatment may result in anorexia and leanness.

The mechanism by which organic brain lesions stimulate the appetite is not clear. For reasons beyond metabolic definition, a reasonable meal does not "satisfy." Hypoglycemia secondary to hyperinsulinism induces hunger in some people, but fails to do so in others. It is rarely a factor in childhood adiposity.

Hypothyroidism (decreased energy metabolism, growth and physical activity) is seldom noted in association with obesity in children.

CLINICAL TYPES OF OBESITY IN CHILDREN

While the degree of adiposity is referable to the caloric balance, the distribution of accumulated adipose tissue may be influenced by endogenous factors.

Simple Obesity—Over 95 per cent of all fat children fall into this group. The only thing wrong with these children is that for personality or environmental reasons they have eaten too much. Studies have revealed that the majority of these children are only children or the youngest child and that many of them are unwanted. In many families the relationship of the parents is unhappy. Food may have taken on exaggerated importance and may become a substitute for love, security and satisfaction.^{4, 5}

A careful survey of the history almost always reveals a period or periods of dietary excess. There is no history suggestive of serious intracranial disease. They are free from symptoms of hypothyroidism. In other words, they are healthy children.

On physical examination fat boys and girls with uncomplicated obesity are usually found to be of average or slightly taller than average stature.⁶ They are of normal intelligence, quite a few stand in the

Fig 173—This 5 year old boy is presented as an example of simple obesity. He was of normal weight at 1 year (11.8 kg). From that time on he gained at a steady and very excessive rate so that by the age of 5 years he weighed 44 kg or about 21 kg more than he should weigh. During this period of rapid weight gain he also grew rapidly attaining a height of 125 cm. at the age of 5 (normal 105 to 116 cm). He is fond of bread, potatoes, cakes, cookies, puddings, candy bars and the like. Other members of the family also have hearty appetites for a brother of 13 years weighs 80 kg (175 pounds) a sister of 11 years weighs 48 kg (105 pounds) and his father who is 170 cm. (5 feet 8 inches) tall weighs 100 kg (220 pounds). He is of normal intelligence and is free from symptoms of increased intracranial pressure. There is nothing in the history to suggest hypothyroidism. Aside from the excessive accumulation of subcutaneous tissue and tallness in stature, physical examination is not remarkable. The blood pressure is 120/80. Roentgenograms of the skull show a normal sella turcica and fail to reveal any abnormalities. Roentgenograms of the hand and wrist show that his skeletal development corresponds to the average normal for his chronologic age. The urinary 17 ketosteroid output is 0.6 mg. per day a normal value. By the simple expedient of reducing his intake of starchy foods to one half piece of bread or its equivalent per meal three times a day he is losing weight at the rate of about 0.5 kg (1 pound) per month.

top third of their class at school. Some of these children are found to be only moderately plump while others are extremely fat (see Figs 173 and 174). The excess adipose tissue though generally distributed often accumulates especially in the region of the breasts, hips and lower abdomen. Though the breast regions may thus appear enlarged, palpation usually fails to reveal any true mammary gland development.

Fig 174—A, Extreme example of simple obesity in a boy of 6 years weighing 65 kg and measuring 126 cm and with genu varum probably secondary to excess weight bearing. During a period of 8 months on a caloric intake of from 1000 to 500 calories per day, he lost 29 kg. B, The administration of thyroid had essentially no effect upon the rate of weight loss. During this period the genu varum was corrected by bilateral osteotomies.

except in adolescent girls. A transient and apparently physiologic development of the mammary tissues is noted in a small number of normal adolescent boys.

The eyes, extraocular movements, visual fields and eyegrounds are normal. While the chest and heart are normal, the blood pressure may be slightly elevated. In this respect it is helpful to remember that the

use of a blood pressure cuff which is too small for the patient's arm will result in an overestimation of the blood pressure. The abdomen is free from abnormal masses. The genitalia in boys often appear to be small because they are embedded in a thick pad of pubic fat. By pressing the fat aside, this erroneous impression can be dispelled. In this connection, it is noteworthy that in normal boys the genitalia remain of essentially infantile size until approximately 11 to 12 years of age.⁷ Not until that time do the testes secrete enough male hormone to stimulate any significant development of the masculine secondary sex characteristics. Moreover, some normal boys develop one or two years later than the average. For these reasons boys need not necessarily be considered hypogonad even if genital growth is delayed to the thirteenth or fourteenth year. Sexual development is moderately accelerated in some of these children.⁸ The skin is smooth, warm, moist and of normal color. Apparently as a consequence of stretching of the skin striae over the hip regions are occasionally seen. In contrast to the striae of Cushing's syndrome which are purple, these are pinkish white. There is no pathologic hirsutism. The extremities are normal.

in one individual, the resultant combination is sometimes called the Laurence-Moon-Biedl syndrome

Like normal children, these patients are fat because they have eaten relatively too much. It is postulated without much factual basis that these excessive appetite may be due to a hypothalamic lesion.

Obesity in Association with an Expanding Intracranial Lesion (Fröhlich's Syndrome)—This is a rare condition usually due to a craniopharyngioma or suprasellar cyst.¹⁵ Children suffering from this disease present

Fig 175 —Obesity in a 9 year old boy with a suprasellar cyst. Note the strabismus

such typical symptoms and signs of an expanding lesion in the region of the optic chiasm as headache, vomiting, disturbances of vision (bitemporal hemianopsia) or of extraocular movements, optic atrophy, separation of the cranial sutures and increased spinal fluid pressure (Fig 175). Roentgenograms of the skull may reveal erosion of the sella turcica or an area of calcification in the neighborhood thereof.

These expanding lesions apparently influence the appetite in much the same manner that experimentally produced hypothalamic lesions

do They may also interfere with the function of the anterior and/or posterior pituitary gland either directly by causing pressure atrophy of the gland or indirectly by interfering with normal neurohypophyseal regulatory mechanisms

When the anterior pituitary function is impaired, various disturbances in growth and development may be noted Interference with the production of the growth hormone results in dwarfism Failure to produce the thyroid-stimulating hormone results in hypothyroidism which leads to retardation in growth and in skeletal maturation When there is failure to produce the anterior pituitary gonad-stimulating hormones, the gonads themselves remain infantile and little or no secondary sexual development occurs Finally, lack of the anterior pituitary adrenal-cortical stimulating hormone results in atrophy of adrenal cortices and the development of Addison's disease In a given patient there may be a complete or only partial impairment in the production of any one or more of these anterior pituitary hormones Hence, patients with destructive lesions in the region of the hypothalamus or the pituitary may present a variety of clinical pictures In fact, certain lesions which affect the hypothalamus but leave the anterior pituitary intact sometimes lead to precocious growth and development Hypothalamic stimulation of the anterior pituitary is believed to be responsible for such precocity

In so far as hypothalamic lesions stimulate polyphagia, they may be considered as factors predisposing to obesity There is no evidence that they induce adiposity by other mechanisms Similarly it is fair to say that there is no such thing as "pituitary" obesity Many patients with destructive lesions of the pituitary actually suffer a marked loss of appetite and as a consequence become cachectic (Simmonds cachexia)

Though the foregoing types of intracranial lesion have received much publicity, other intracranial conditions such as *internal hydrocephalus*, brain tumors, xanthomatosis, pinealoma, syphilis, poroncephaly and postencephalitic changes likewise may lead to obesity and to disturbances in obesity and development

Obesity in Association with Hypoglycemia—Hypoglycemia resulting from hyperinsulinism or from glycogen disease induces overeating in some individuals Such conditions as these are but rarely encountered in pediatric practice An abnormally low fasting blood sugar value is suggestive of hyperinsulinism Hepatomegaly, ketonuria and hypoglycemia are suggestive of glycogen storage disease.¹⁰ Patients with this condition show very little elevation of the blood sugar concentration following the administration of adrenalin.

Obesity in Association with Hypothyroidism—It is unusual to discover hypothyroidism in an obese child This is explained by the fact that hypothyroidism tends to cause a *diminution* in appetite as well as a decrease in the total energy metabolism, physical activity and growth.

The most characteristic symptoms of thyroid lack in children are easy fatigability, both physical and mental, constipation, sensitivity to cold weather and slowness in statural growth. On examination almost all hypothyroid children are found to be of dwarfed stature. Mental deficiency is not a consistent finding. The skin is pale, coarse, cool and dry. There is often a subtle appearance of puffiness around the face due to local accumulations of myxedema fluid. Accumulations of myxedema fluid in other localities may also give rise to a pudgy appearance.

Roentgenograms of the hand and wrist reveal a retardation in the skeletal development. In children this diminution in bone growth is associated with a lowered serum phosphatase value (less than 45 Bodansky units per 100 cc)¹⁷. An elevation in the serum cholesterol concentration above 250 mg per 100 cc is also suggestive. However, in many hypothyroid children who have never received thyroid medication, this value is either normal or low rather than elevated. On the other hand, when such hypothyroid children are given adequate doses of thyroid (1 to 2 grams of USP thyroid daily) for a month or longer and then their medication is discontinued, they develop hypercholesterolemia within the next one to three months. Children with normal thyroid function do not do so.¹⁸ The basal metabolic rate is much less reliable as an index of hypothyroidism in children than in adults. Possibly the best index of thyroid function is the concentration of protein-bound (thyroid hormone) iodine in the plasma or serum. This should receive increasing attention as more laboratories become equipped to make the determination.

Obesity as Effected by Other Endocrine Disturbances—Certain steroid hormones of the adrenal cortex and possibly of the sex glands may exert a striking influence upon the distribution of body fat. The outstanding example is *Cushing's syndrome* (Fig 176), a rare condition which is thought to be due to an excess of those adrenal cortical hormones which accelerate gluconeogenesis from protein.¹⁹

This condition may occur at any age.^{20 21} The youngest recorded patient was only eleven weeks old. The incidence is considerably greater in girls than in boys. The obesity is often, not always, of the "buffalo" type. That is, there is a marked accumulation of fat about the head and neck, while the extremities are relatively lean. Muscular weakness is a characteristic finding. The cheeks in the characteristic patient are plethoric in appearance. There are purplish striae in the skin over the hips, abdomen and thighs, acne is common especially in older girl patients. There is often generalized hirsutism. The genitalia may be precociously developed. Hypertension is an outstanding finding. This is reflected by the plethoric appearance already mentioned and may also be manifested by cardiac enlargement and occasionally by cerebral hemorrhages. When the disease is due to an adrenal cortical carcinoma, an abdominal tumor may be palpable.

Intravenous pyelograms may be helpful in revealing such tumors. There is a decreased tolerance for sugar and a tendency to insulin resistance.¹⁰ In some patients there is a marked increase in the urinary excretion of 17-ketosteroids, in others, the values are essentially normal.^{10 2-} Osteoporosis of the spine especially is a notable sign. The skeletal development tends to be normal for age and sex.

Fig 176.—Cushing's syndrome in a 12 year old girl. (Courtesy of Dr F Albright.²⁰)

Though not so clear-cut, there is also some evidence to suggest that the testicular male hormones favor a distribution of fat in the upper segment of the body while the ovarian female hormones cause the fat to be distributed in the lower body segment. Most preadolescent children show a fairly even distribution of fat when they become obese. Hypogonadism per se does not cause obesity.² Obesity, on the other hand occasionally retards the onset of adolescence. In this respect it is of interest that simple weight reduction by dietary means often results in prompt adolescent development in children with simple obesity.

COMMENTS ON THE CLINICAL STUDY OF OBESE CHILDREN

In view of the fact that obesity, though not a metabolic or endocrine disease per se, may be a sign of some important associated condition, it is desirable to emphasize certain parts of the history and physical examination of fat children. Thus, in the history, symptoms of intracranial disease, physical inactivity, hypometabolism, mental deficiency or family maladjustments may be helpful. In the physical examination, signs of increased intracranial pressure, abnormal eyegrounds, a marked hypertension, an abdominal tumor, skeletal anomalies, a "buffalo" distribution of fat, muscular weakness or shortness of stature may lead to a specific diagnosis.

The value of a careful examination of these patients is well exemplified by one patient who superficially appeared to be a typical example of simple obesity. However, routine examination of the eyegrounds revealed unmistakable papilledema. That child was subsequently found to have a brain tumor.

Roentgenograms of the skull occasionally reveal abnormalities not previously evident. Roentgenograms of the hand and wrist permit an estimation of the skeletal development which is helpful when deviations in the rate of maturation are suspected. Fasting blood sugar determinations as well as glucose and glucose-insulin tolerance tests²³ may be helpful occasionally. Likewise, in the patient suspected of having adrenal cortical disease, a urinary 17-ketosteroid measurement can be diagnostic. Determinations of the basal metabolic rate are seldom helpful and often lead to an erroneous diagnosis of hypothyroidism. Other means for establishing a diagnosis of this disease have been discussed above.

TREATMENT OF CHILDHOOD OBESITY

General Considerations—One of the first considerations in treatment is the question, is it worth while to attempt to reduce the body weight of all fat children? The answer depends partly upon the type and degree of obesity. Because children are growing individuals, it sometimes suffices merely to prevent further gains in weight. A quantity of fat which was moderately excessive for a small child will be normal for the same child when he is a few inches taller. On the other hand, a markedly excessive accumulation of fat may interfere with the physical efficiency of a child to such an extent that participation in normal childhood pursuits is greatly impeded. Furthermore, as mentioned earlier, adiposity per se occasionally retards adolescent development, an occurrence which may cause considerable concern to patients and their parents.

As indicated in the introduction, any person will lose weight when the caloric intake is consistently less than the caloric output. In general, it is more profitable to produce such a caloric deficit through

reducing the caloric intake (underfeeding) than by increasing the caloric expenditures with the aid of exercise and/or medications. It requires a considerable amount of exercise to increase the total caloric output significantly. Thus, even for an adult man weighing 70 kilograms an hour's walk on a level road at a rate of about 3 miles per hour requires only 160 calories or 17 gm. of fat.²⁴ Vigorous exercise tends to stimulate a voracious appetite. After underfeeding is instituted there may be a one or two week interval before a loss of body weight occurs. This is explained by the fact that while the patient loses fat during this period, he retains an equal weight of water.² Sooner or later there is a spontaneous diuresis with the loss of one or more kilograms of weight during the course of a few days. Thereafter weight loss is steady.

How can one induce a child to eat less? In younger children whose diet is completely under the control of their elders, this may not present too great a problem. In the older and more independent child, success depends largely upon gaining the interest and cooperation of the patient. Without these, attempts at therapy are usually a failure. In other words, the problem is a psychological one. Frequently the primary fault lies chiefly with parents who need advice on the management of children. On the other hand, the child often needs to develop pride in his appearance, a feeling of self-confidence and an appetite for something more important than food.

Dietary Therapy—Regimen A—This regimen permits eating any reasonable quantities of protein and other relatively low caloric foods while forbidding the eating of certain high caloric items.

1 Eat no candy, cakes, cookies, jams or sugar and no desserts to which such ingredients or flour have been added in any considerable amount.

2 Eat not more than one-half piece of bread (any type) a meal or its equivalent in rice, macaroni, spaghetti, potato or other starchy food.

3 Drink 2 to 3 glasses of skimmed milk a day.

4 Except for these instructions, eat as desired at mealtimes of lean meats, fish, colored vegetables, salads, fresh fruits. Use vinegar or mineral oil dressing. Use ordinary common sense in not stuffing on any particular diet.

5 Plan to eat three reasonable meals a day. The individual who eats no breakfast, a small lunch and a huge dinner tends to gain more weight than the person who eats the same amount of food divided equally between three meals.

In favor of this regimen is its simplicity and the fact that individuals on it are less tempted to eat the forbidden because they feel starved. While it suffices in many instances at least to prevent further weight gains it is ineffective in others. When a more precise adjustment of the caloric intake is desired, diets similar to those of Regimen B may be prescribed.

Regimen B—It is appropriate to offer a diet calorically equal to the basal energy metabolism. For practical purposes this may be predicted roughly from the ideal weight for the patient's height as follows:

Height, cm	Ideal Body Weight, kg	Basal Heat Production, Calories per day ^{2b}
73	10	550
115	20	870
137	30	1100
150	40	1250
160	50	1400
170	60	1550

Provided the mineral, nitrogen and vitamin requirements are met, patients suffer no damage from such underfeeding so long as excess body fat remains

Sample diets* follow

- 1 750 cal., P 53 gm, F 20 gm, CHO 90 gm

Breakfast

- a Orange juice, $\frac{1}{2}$ cup
- b Toast, $\frac{1}{2}$ slice, or cereal, $\frac{1}{2}$ cup
- c Butter or oleomargarine, $\frac{1}{2}$ square

Noon

- a Clear soup (broth, bouillon or consomme) ad lib
- b One egg or lean meat, fish, fowl or cottage cheese, 2 oz. or 5 table-spoons or a piece about $\frac{1}{2} \times 2 \times 3$ inches
- c. Vegetables, 2 servings ($\frac{1}{2}$ cup each) raw or cooked without sauces
- d Fruit, $\frac{1}{2}$ cup or equivalent.
- e Skim milk, $\frac{1}{2}$ cup

Night

Same as at noon, but add $\frac{1}{2}$ slice bread and $\frac{1}{2}$ square butter

- 2 1000 cal., P 68 gm., F 30 gm, CHO 115 gm

Add to regimen 1, 1 cup skim milk, 1 slice bread, 1 egg, $\frac{1}{2}$ square butter

- 3 1200 cal., P 70 gm, F 51 gm, CHO 115 gm

- * Substitute $2\frac{1}{2}$ cups whole milk for the skim milk of regimen 2

The following suggestions as to the choice of foods may be helpful *Vegetables* A serving of potatoes, kidney, lima, navy or soup beans and of corn shall be considered as $\frac{1}{4}$ instead of $\frac{1}{2}$ cup Lettuce and celery may be used ad lib All other vegetables equal $\frac{1}{2}$ cup *Fruits* No sweetened fruit is to be used Unsweetened canned fruits can be purchased A serving of banana is $\frac{1}{2}$ a small banana *Meats, etc.* All visible fat is removed Ham, pork, bacon, wieners and picnic meats not allowed Obviously fat fish, such as those packed in oil and such as mackerel, shall not be used All cheese except cottage cheese is prohibited *Method of Preparation* Cook all foods without fat unless that allowed for the meal is used Broiling, steaming or boiling is the method of choice for cooking meats No flour gravies or sauces are allowed At least one vegetable a day should be served raw *Other Foods* Prohibited¹

Other Therapy—Benzedrine sulfate (amphetamine sulfate) may be helpful in controlling the appetite It should be given one-half hour before meals The recommended adult dose for chronic medication is usually 10 mg repeated three or four times daily An appropriate fraction of this dose may be given to children Since occasional patients

* We are indebted to Miss S Wells, dietitian in charge at the Metabolic Ward of the Massachusetts General Hospital, for these diets

are sensitive to the drug and develop cerebral symptoms, the initial dose should be small. A tendency to increased appetite has been noted after discontinuation of the drug and the effect may be only temporary.^{7b}

Thyroid therapy is disappointing except in the rare obese child who is suffering from hypothyroidism. The administration of this hormone to euthyroid fat children often results in an increased appetite—a reaction which, unless carefully controlled, is clearly undesirable. In sizeable doses it also tends to cause such symptoms and signs of thyrotoxicosis as nervousness, excitability, tachycardia, sweating, tremors, diarrhea and even demineralization of the skeleton and protein depletion.

Obesity is not ordinarily an indication for sex hormone (testosterone, estrogen, etc.) or anterior-pituitary-like (chorionic gonadotropin) therapy. As mentioned above, most fat children mature sexually in a normal manner. In some this process is expedited by simple dietary weight reduction. A discussion of the therapy of significant hypogonadism and of Cushing's syndrome is beyond the scope of this article.

PRACTICAL PSYCHIATRY

HARRY C. SOLOMON, M.D. *

NEW METHODS OF THERAPY IN PSYCHIATRIC DISORDERS

THERE are several therapeutic processes that have been developed by psychiatrists and are specially applicable to the field of psychiatry. Therapies of some particular interest may be listed chronologically according to the time of their origination (1) psychotherapy, (2) treatment of neurosyphilis and especially general paresis, (3) insulin shock therapy, (4) convulsive shock therapy, and (5) bilateral cerebral lobotomy. The last three methods may be said to have developed largely on an empirical basis and it has been by the trial and error method that certain conclusions have been reached as to the conditions for which they are most applicable. Enough experience has now accumulated, however, to allow us to make some rather definite statements as to the diagnostic conditions in which each of these five methods of treatment is to be used.

Psychotherapy, which may be broadly defined as a method of treatment depending upon the relationship between physician and patient, utilizing the interview method, having many variations in its specific techniques but based primarily on the concepts of a dynamic psychology, has a very broad application to the mental and emotional problems of mankind. However, its most specific values are obtained in personality maladjustments, psychoneurotic manifestations and in somatic disorders in which emotional conflicts play a large role either as the main etiological factor or because of secondary complicating factors (generally named psychosomatic disorders). Psychotherapy to be sure has its place in the treatment of all mental and emotional disturbances, but in many of the psychoses it is hardly an all-sufficient specific methodology.

The treatment of neurosyphilis from the psychiatric standpoint, especially brain syphilis and the specific category of general paresis, depends upon the proper utilization of fever therapy, chemotherapy and penicillin. This problem will not be discussed in the development of this clinical discourse.

Insulin shock therapy which was developed by Sakel has proved to be of distinct benefit in the treatment of the schizophrenic disorders. After as long as fifteen years of wide experience with this treatment method the actual value is not definite. However one can assume it has the capacity of improving the prognostic outlook of

Medical Director Boston Psychopathic Hospital Professor of P
Harvard Medical School, Boston, Massachusetts.

the cases of schizophrenia in its early period. The best figures available at the present time are a result of a careful survey made by a special commission appointed by the Governor of the State of New York. The results of this survey, which compared the outcome of treated cases with a control group as similar as possible but which did not receive insulin shock therapy, indicated that the patients treated had about one and one-half times a greater probability of leaving the hospital greatly improved, if not recovered, that they had a greater chance of remaining well than had the control group, and if they did relapse improvement again was more likely to occur in those originally treated. It may, therefore, be given as a working hypothesis that patients with schizophrenic disorder have a certain recoverable tendency which may be materially increased by this type of treatment.

Convulsive shock therapy was originally introduced by von Meduna. Convulsions were produced by the intravenous injection of metrazol. Later a modification of the method of producing the convulsions by passing an electric current through the brain was perfected by Bini and Celletti. Convulsive shock therapy has proved to be of great value in terminating depressive and agitated states. In typical instances of the depressive phase of the manic-depressive psychosis four to twelve convulsive attacks will produce a complete cessation of the disorder in at least 80 per cent of the patients so treated. It also has a considerable value in terminating the disorder in patients in the manic phase. Its value is even more striking in the treatment of patients in the middle and older age groups suffering from agitations. In these patients the normal course of the psychosis is chronicity in almost 50 per cent and a long-continued psychosis of one to four or more years in the remainder, but with the convulsive shock treatment 60 to 70 per cent of these patients are quickly improved. In other words, many who would otherwise be incurable are made well, and many who would have a very long period of mental disorder are returned to good functioning capacity and happy contentment in the course of a few weeks at most.

The *prefrontal lobotomy* operation has not been used long enough nor has it been done in sufficient numbers to indicate with certainty the cases in which it offers the most benefit. Nevertheless, one can state that it offers a high probability of affording relief and returning to a much better status of efficiency and joy of living many of the chronic agitated patients who respond to no other form of treatment. Further, one finds that not a few chronic schizophrenic patients are greatly improved. It also has a distinct value in certain severely disturbed obsessive-compulsive neurotics. Many patients of this latter group in which all other forms of treatment, including long periods of psychotherapy, insulin and convulsive shock therapy had failed, have been greatly improved by the lobotomy operation. This operation, of course, is a very mutilating one which destroys to a considerable extent the integrity of the brain and does some damage to the

personality of the individual. It, therefore, is obviously to be used only when other and simpler methods are not practical, and when the choice between the continuance of the symptoms and the damaging results of the operation favor the latter.

IMPORTANCE OF CORRECT DIAGNOSIS

From the above discussion it would seem to follow logically that these several methods of treatment are to be used for rather specific types of disorder. It follows therefore, that good diagnostic discrimination becomes an essential in the psychiatric management and treatment of patients. Unfortunately, there are no specific tests except in neurosyphilis which allow for a careful check of clinical diagnosis. Diagnosis must depend in most instances upon the proper evaluation of history, physical and psychiatric examinations. In other words, it depends upon the clinical acumen, experience and judgment of the physician. At this period of the practice of psychiatry when these several methods of treatment are available, none of them being easy, cheap or free from damage, it is obvious that if any one is to be used a high degree of diagnostic skill and first-rate judgment become of the utmost importance.

The remainder of this discussion will attempt to show the importance of correct diagnosis as a preliminary to the application of treatment methods and indicate the seriousness of mistakes.

It has been stated that the convulsive shock therapy is of great benefit in the treatment of depressions and the agitated states. In these conditions psychotherapy has a limited applicability. To be sure there is a considerable amount of difference in the opinion of psychiatrists on this point, but almost all would be in agreement that psychotherapy is a slow, cumbersome and often bad tool in cases of depression during the course of the disorder. On the other hand convulsive shock therapy is probably contraindicated in cases of psychoneurosis. Indeed, in most instances the psychoneurotic rather than benefiting from a course of such treatments is likely to become more tense, more worried, more concerned about himself, which is an addition to the potential dangers inherent in the method. Many times it is extremely difficult to make a differential diagnosis between beginning depression or agitated state and a psychoneurosis. Often the configuration of a depression is that of neurotic symptoms. The following case may well illustrate these points.

Alex. F. is a 27 year old woman married to a soldier who was stationed in the Pacific area. She had always been a reasonably well endowed and well adjusted individual, although perhaps unduly dependent upon her strong willed and efficient mother.

She nursed her mother very attentively during a couple of months of a terminal state of carcinomatosis. Following her mother's death she went to live with an aunt who developed a small tumor of the breast, very similar to the

first symptom in her mother's case. Upon our patient developed the responsibility of insisting that her aunt be operated upon. The pathological examination indicated that the growth was benign.

Following this experience our patient began to complain of great fatigue, had disturbed sleep and began to worry about her somatic state. She complained of pains in various parts of her torso, began to fear that she herself had a malignant disease. She was hospitalized for two and one-half weeks in one of our best general hospitals. A painstaking inventory of her anatomy and physiology was made. X-rays, blood tests and almost every known laboratory procedure were given her. At the end of the two and one-half weeks of observation and examinations the diagnosis of psychoneurosis was offered and was confirmed by the psychiatrist.

Rather intensive psychotherapy was carried out by an able psychiatrist for two and one-half months without improvement. It was then considered advisable to transfer her to another psychiatrist who worked with her for several weeks more, when her symptoms became more marked. Agitation became so evident that she was admitted to the Boston Psychopathic Hospital. At the hospital a diagnosis of an agitated depression was made. Consequent upon this diagnosis, convulsive shock therapy was given. At the end of one week, after three convulsive treatments, the patient was greatly relieved, and after nine such treatments the patient was a gay, happy, unconcerned woman, able to take her place at home, with practical freedom from symptoms, and once more enjoying life to the fullest.

It seems indeed probable that had the correct diagnosis been made early, convulsive shock treatment applied at once would have resulted in the prompt alleviation of all symptoms and thereby saved the patient much suffering and disability. It would also have saved many hours of physicians' time. On the other hand, had the diagnosis of psychoneurosis been the correct one it would have been inexcusable to have given convulsive shock therapy.

Perhaps an even more striking case is that of a 53 year old, unmarried woman who came to the Boston Psychopathic Hospital after several months of increasing disability and discomfort. On entrance to the hospital the patient was complaining bitterly of gastric distress, nausea, vomiting and distaste for food. She likewise complained of headache, mild dizziness and generalized aches and pains. She slept very poorly, was constantly requesting sleeping drugs, and even with fair amounts of these slept but little each night. She presented a syndrome with which we are all so familiar, namely that of the complaining, whining, distressed neurotic.

However, we had known this patient at the hospital previously. Twenty years ago she had been a patient here for fourteen months, with rather similar symptomatology. Prolonged and intensive psychotherapy of fourteen months' duration accomplished little or nothing and she left the hospital to remain at home an invalid for another two years, so that her total illness on that occasion lasted more than three years, during which time she was incapable of looking after herself adequately, certainly incapable of work, and suffering much torture.

Nor was this her first disability—in fact, at the age of 16 she had had a long illness diagnosed as a psychoneurosis.

Her history indicated, however, that these disorders, in contrast to the usual story of the typical psychoneurotic, were distinctly delimited, and in the long intervals between these attacks she was a very able, hard-working, energetic person.

Based upon the history of this patient and the total over all picture, the diagnosis on her recent entry to the hospital was that of a depression of manic-depressive type. Indeed this was the final discharge diagnosis twenty years ago, after fourteen months of observation. Therefore without lengthy observation, at the end of approximately a week of hospital stay during which no improvement was attained she was started upon convulsive shock therapy. After two such treatments her sleep improved and she began to show fewer signs of restlessness. In the course of ten days she was relatively comfortable, able to be about the ward taking part in general hospital activities, and at the end of a month she was able to go out and look after herself feeling greatly relieved and once more a hopeful person with an enjoyment of life.

This case illustrates the difficulties of psychotherapy with the depressed patient. It also illustrates the great effectiveness of the convulsive shock therapy in this type of disorder, but, more to the point, it illustrates the diagnostic difficulties in separating the depressive agitated state from that of the anxiety state of the typical psychoneurotic.

If it be true that the psychoneurotic patient does not improve with convulsive shock therapy, which experience seems to indicate is generally the case, and if the majority of the patients in the depressive agitated category respond so well to convulsive shock treatment, it may be assumed that this type of treatment offers diagnostic possibilities. It is probably true that this method might be used as a therapeutic test of diagnosis. Only rarely, however, would this seem to be justified because of the inherent danger of the treatment, and it should not be used unless one has a good basis for belief that it will be beneficial, nor is it by any means a completely satisfactory diagnostic tool, for some patients with a depressive disorder fail to respond adequately to a considerable number of such treatments.

The following case history will document this statement.

Miss V. C. was a young woman of 22 who was taking nursing training when she became uninterested in work and in life. She complained more and more of fatigue. This led to a very careful physical inventory of two weeks duration in a general hospital, at the end of which time a diagnosis of psychoneurosis was forthcoming and on the basis of this diagnosis she was sent to the Boston Psychopathic Hospital for treatment.

She remained at the hospital a number of months, at first being considered as suffering from a psychoneurosis and given quite intensive psychotherapy. As a result of continued study and the lack of progress, the diagnosis was changed to that of manic-depressive depression and she was given ten convulsive shock treatments without notable improvement. Further consideration led to the conclusion that she was suffering from a schizophrenic disorder. On the basis of this diagnosis frontal lobotomy was suggested. The suggestion was not accepted by the family and she left the hospital unimproved. The later course of her disorder indicated strongly that she was indeed suffering from a manic-depressive disorder because she became quite hypomanic and then made a good recovery.

On the case material presented one might perhaps draw two conclusions: (1) that the differential diagnosis between depressions and psychoneuroses is by no means easy to make and (2) that

are frequent disorders. While such assumptions would be unjustified on the basis of this small amount of selected material, yet such are the facts. Mild depressions are more common than most people realize, in fact, they are one of the most common disorders to be met in any clinic due to the fact that the early presenting symptoms are so often related to somatic complaints. The disorder frequently begins with the patient complaining of fatigue, headache, dizziness, visual difficulties, loss of appetite, various gastro-intestinal symptoms, shortness of breath and fear of various diseases. It is unquestionably a fact that many therapeutic successes are more the result of the spontaneous recovery of the depression which has been erroneously diagnosed than of the success of treatment, whether medicinal or psychotherapeutic in kind.

As the last case suggests, the diagnosis of schizophrenia is also often incorrectly made both positively and negatively. Schizophrenia often starts with symptoms that closely resemble the psychoneurosis. It is very common to find a psychoneurotic-like syndrome as the premonitory symptoms of the schizophrenic disorder continuing for many months before the more sinister symptoms are readily evidenced.

M. S. at the age of 17 began to be disturbed about sensations around his heart. In the course of a year he saw several internists who, after careful examination of the cardiac organ, assured him that there was no organic disease. This assurance had no effect upon the patient. He continued to worry and fret about his heart, became more and more concerned therewith, quit work and became increasingly irritable. It finally became evident that he was suffering from schizophrenia. After six years in a state hospital for mental disease, during the latter two of which he was completely mute, a bilateral lobotomy operation was performed, with a moderate degree of improvement. He then told the story that his original concern about his heart was instigated because he believed that he had been damaged through the means of an evil eye.

Although the value of bilateral lobotomy in the treatment of schizophrenia has not as yet been well established, it seems not unlikely that in many instances it is the treatment of choice. An early diagnosis for the proper evaluation of treatment, whether convulsive shock, insulin shock or lobotomy, is as important in this disorder as in any other in the field of medicine.

Diagnosis on which proper selection of therapy depends is important in psychiatry as in other fields of medicine. However, as the delay of a few weeks in the institution of therapy is not of critical importance, one is able to have a considerable period of observation and study of patients before coming to a final decision. During such a period of study one is actually beginning psychotherapy. The relationship of physician and patient is a most important portion of the therapy. Likewise, the interviews which represent an essential and basic part of the examination method are in themselves therapeutic. In the process of the examination the patient has the opportunity to

ventilate many emotional complexes, and often is thereby enabled to gain a considerable amount of insight into his disorder. Repeated diagnostic interviews, which are at the same time of therapeutic value and which require hours of time, are comparable to prolonged study in physical disease which utilizes many laboratory techniques.

Training and experience on the part of the psychiatric diagnostician and therapist are essential if adequate results are to be expected. Any physician who is willing to expend time and energy to study problems in the psychiatric field can fit himself to make diagnoses and to carry out treatment. There is no necromancy in psychiatry. It may be pointed out in this respect that even necromancy takes a great deal of practice before any perfection in the magician's art is attained. Some men because of manual dexterity may excel as surgeons and some men because of their own sensitivities and sympathies may be better psychiatric therapists than others. Nonetheless, every physician can have a considerable competency in diagnosis and treatment in this field. Such competency is an essential for the first-rate practice of comprehensive medicine, and once more it must be emphasized that this can be attained only through training and experience.

It is hoped that the preceding discussion makes clear that inadequate diagnosis can lead to serious errors in regard to human life and happiness.

ACTIVE IMMUNIZATION AGAINST SOME COMMON COMMUNICABLE DISEASES

MATTHEW A. DEROW, M.D. * AND SANFORD B. HOOKER, M.D. †

THE number of infectious diseases against which specific protective measures are available is increasing rapidly. In some the need for prophylactic immunization is limited to persons of special occupational or geographical groups. Thus, inoculation against yellow fever is hardly of interest to residents of regions where the specific mosquito vector is absent. Similarly, Rocky Mountain spotted fever is a risk only to those whose occupation or habitat exposes them to possible bites by infected ticks. In others of practically universal distribution eventual exposure to possible infection is likely for almost everyone. Many of these are the so-called "diseases of childhood," essentially because children form the largest group of nonimmunes. Adults are relatively free by virtue of immunity resulting from recovery from the clinical disease or from the stimulus of repeated subclinical infections. Prominent in this category are whooping cough, diphtheria, scarlet fever, measles, chickenpox, typhoid fever and smallpox. In some, particularly typhoid fever, smallpox and diphtheria, the decreased incidence of the disease as a result of improved sanitation and fairly widespread immunization lessens the chance of an adult's being naturally immune and makes imperative the acquisition of protection by artificial active immunization. In still others of comparatively low incidence the very high case-fatality rates make them serious problems in the event of possible infection. Tetanus and rabies are good examples of these.

Of the available procedures, therefore, certain ones stand out as highly desirable for routine application in the population at large. Those considered here are applicable in the prevention of smallpox, diphtheria, whooping cough, scarlet fever, tetanus, the enteric fevers (typhoid and paratyphoid) and rabies. The first five of these diseases are of primary risk to children and protection should be established not later than the twelfth month of life. To delay immunization against these until the child's entry into school is to deny protection when it is most needed, as by far the majority of deaths occur in the pre-school ages. With the present large shifts of population and the habit of vacationing in localities whose state of sanitation may be at best doubtful, more widespread immunization against typhoid and paratyphoid fevers is advisable. Antirabic vaccination is a special prob-

lem, associated with animals' bites (usually dog bite), that all too commonly confronts the physician

MEANS OF MINIMIZING THE DISCOMFORT ASSOCIATED WITH INJECTIONS

In carrying out any prophylactic measure a primary objective is to avoid making the subject ill through the attempt to prevent illness. Oversight of this principle is hardly constructive propaganda for universal prophylactic immunization. Attention to certain details, some of them apparently trivial and too often overlooked, can do much to minimize objectionable discomfort associated with injections

1 An all glass 1 cc tuberculin syringe, graduated in hundredths of a cubic centimeter, is best for use in immunization. For skin tests and for measuring fractional doses it is almost indispensable. For the occasional dose greater than 1 cc., the usual 1 5 or 2 cc all-glass syringe graduated in tenths is satisfactory

Needles of 25 or 26 gauge are large enough for any immunizing injection. They must be smooth and sharp. There is no excuse for the use of dull, hooked or rough needles, which only serve to make difficult and painful what should be a simple and often painless procedure.

2 Sterility of syringes and needles must be scrupulously accomplished and maintained. The safest handy method is *boiling* for not less than fifteen or twenty minutes. The syringe and needle should not be assembled until after sterilization. This is best done with a forceps that can be flamed before it touches the sterile instruments. A sterile test tube (boiled with the syringe and needle) for protection of the exposed needle until use is advisable.

The widespread use of alcohol for sterilization of hypodermic syringes and needles is to be deprecated, firstly, because alcohol (even 70 per cent by weight) is at best a poor disinfectant, secondly, because many immunizing agents are injured or destroyed by the traces of alcohol remaining in the syringe and needle, and thirdly, because of the unnecessary pain caused by the injection of even these small amounts of alcohol

3 Practically all immunizing agents are now packaged in rubber-capped vials. The cap must be sterilized by wiping with a potent, non-corrosive skin disinfectant. After the cap has dried, the needle is inserted and a volume of air equal to the amount to be withdrawn is injected. The vial and syringe are then inverted and the required dose is withdrawn. In the case of vaccines or precipitated antigens the material must be well shaken to insure uniformity of the suspension before the required volume is withdrawn

4 Most inoculations are best made in the region of the insertion of the deltoid or triceps muscles. These sites are convenient, and because of the looseness of the surrounding tissues discomfort due to volume

of material introduced, or subsequent slight edema or induration is kept to a minimum. Injections in a series should be alternated from arm to arm so as not to cause irritation by repeated inoculation into the same site. Inadvertent intravascular injection of some materials may give rise to disagreeable (occasionally serious) reactions. To prevent this, tension should be exerted on the plunger of the syringe after insertion of the needle beneath the skin. If blood appears in the hub of the syringe the needle is withdrawn and injection is made at another site.

Preparation of the site of injection requires surgical sterility. Diluted tincture of iodine (wiped off with alcohol to prevent possible burns) or the organomercurial tinctures are satisfactory for this purpose.

5 Individualization of treatment is a *sine qua non* in producing immunity with minimal discomfort to the subject. Printed directions must be considered as general guides to effective dosage, not as rigid, inviolable dicta. Where possible, precautionary tests should be done and as in all medication dosage should be modified in accordance with the age and weight of the patient. Above all, after one dose subsequent doses must be guided more by the previous reactions than by the printed label.

In order intelligently to individualize treatment one must have knowledge not only of technic but also of the nature and mode of action of the materials used. It is from this point of view that the following summaries have been prepared.

DIPHTHERIA

Principle—Active immunity against diphtheric toxin is produced by the injection of toxoid or toxin-antitoxin.

Material—1 *Toxoid* is toxin that has been modified so as to destroy its poisonous properties while retaining its ability to evoke antibody formation. In practice this is usually accomplished by prolonged incubation with dilute formaldehyde. For use in immunization against diphtheria, toxoid is usually standardized to contain 15 L_r doses per cc., although concentrations as high as 45 L_r doses per cc. have been used. Diphtheric toxoid may be used unaltered as *fluid toxoid* or as *alum-precipitated toxoid*. The latter is toxoid that has been precipitated with sterile alum to yield a suspension of insoluble alum-toxoid flocules. Toxoid is best kept at 5° C (40° F) but is not rendered dangerous for use by inadvertent freezing.

2 *Toxin-antitoxin* consists of a slightly underneutralized mixture of diphtheric toxin and antitoxin. Most preparations are made with equine antitoxin, but both ovine and caprine sera are in use. Experimental mixtures using human antitoxin have been prepared but have not received widespread trial. The mixture contains 0.1 L_r dose of

toxin per cc and is usually 80 to 90 per cent neutralized with antitoxin. Toxin-antitoxin mixtures are best stored at 5° C. (40° F). *Under no circumstances should they be allowed to freeze*, as the toxin may thereby be liberated resulting in a highly poisonous product.

Method—1 Fluid Toxoid—In young children three subcutaneous injections of 0.5, 1 and 1 cc. at three- to four-week intervals produce immunity in almost all cases. After six months, immunity may be tested by the Schick test. If still susceptible an additional injection of 1 cc. is usually sufficient to produce immunity.

Although not as widely used, the *intracutaneous* injection of 0.1, 0.2 and 0.2 cc. of fluid toxoid at intervals of three weeks apparently produces substantial immunity of long duration.

2 Alumi-precipitated Toxoid—Two or preferably three subcutaneous injections of 1 cc. at three- to six-week intervals produce immunity in practically all cases.

Adolescents and adults not uncommonly show local and even systemic reactions to full doses of diphtheric toxoid. It is preferable in these cases to administer only 0.1 cc. of toxoid as a first dose. If no systemic or severe local reaction results the full dosage may be administered for the next two doses. If the reaction be appreciable, subsequent doses should be gauged by the degree of reaction to those preceding. More than three injections will often be required ~~in order~~ to introduce sufficient material to immunize.

3 Toxin-antitoxin—Three subcutaneous injections of 1 cc. are administered at one- to two-week intervals. After six months a Schick test should be performed to see if immunity has been ~~acquired~~. If still susceptible the person requires a repetition of the ~~course of~~ injections.

Comment.—Toxin-antitoxin used in immunization ~~may result in~~ sensitization to the foreign serum present in the mixture. In the exception of occasional adults who show severe ~~reactions to~~ ~~injection~~, there are very few indications for the continued use of ~~toxin-antitoxin~~ in diphtheric prophylaxis. Newer preparations ~~are~~ ~~being~~ ~~designed~~ to minimize the amount of bacterial protein present in the ~~mixture~~ and promise practically to eliminate the unfavorable ~~reactions~~ ~~which may be~~ ~~seen~~ ~~in~~ use in adults and older children.

PERTUSSIS

Principle—Active immunity is produced by the injection of a suspension of dead bacteria

Material—Vaccines are prepared from smooth (Phase I) recently isolated cultures of *Haemophilus pertussis*. The cultures are grown on agar plates or slants enriched with human blood, harvested, and suspended in saline solution containing phenol as a preservative. The concentration of the suspension varies with different laboratories. The vaccines usually available contain

10,000	million organisms per cc	—“single strength”
15,000	“ “ “	—“medium strength”
20,000	“ “ “	—“double strength”
40,000	“ “ “	—“superconcentrate”

Alum-precipitated vaccines are prepared according to the same basic method and then treated with alum to decrease the rate of absorption after injection. These are usually standardized to contain 15,000 million organisms per cc.

In addition to the vaccines described, which have been most widely used, two other preparations are in use. One consists of a suspension of killed *H. pertussis* combined with an “endotoxoid” prepared by treatment of an extract of the organisms. The other is prepared from the soluble toxin of the organism by treatment with formaldehyde to yield a detoxified antigen or toxoid. Both have been reported as satisfactory immunizing agents.

Method—A total of 80 to 100,000 million organisms administered in three or four injections over a period of six to eight weeks is required for effective prophylaxis. The actual volume of vaccine varies with the concentration of the preparation used.

1. *Plain Vaccine*—The schedule which follows is for a suspension of 20,000 million organisms per cc. One, 2 and 2 cc injected subcutaneously at intervals of three to four weeks constitute a course. In older children the last dose may be increased to 3 cc (usually divided into two injections of 1.5 cc in each arm). With a more concentrated suspension the volume should be decreased in proportion. More dilute suspensions require an additional dose or two to avoid injections of unduly large volume.

2. *Alum-precipitated Vaccine*—Three doses of 0.5 cc are administered subcutaneously at three- to four-week intervals. Although the total dosage is only 45,000 million organisms the enhanced action of the precipitated vaccine gives rise to a satisfactory immune response.

Comment—There is no apparent benefit to be gained by the use of vaccines of low concentration that might outweigh the unavoidable increase in number or size of injections. Reactions following the use of the more concentrated vaccines are neither more frequent nor more severe than those associated with the dilute preparations, whereas the

lesser bulk of the former makes the immediate discomfort of the injection much less objectionable.

Prophylaxis against pertussis, though definitely of value in preventing disease in a large majority of children and markedly alleviating attacks in the remainder, is not comparable to immunization against diphtheria or smallpox in respect to the degree of protection produced. However, a stimulating dose of vaccine two or three years after the primary immunization should suffice to carry most children safely through the period of greatest risk from this disease. A small dose (0.10 to 0.20 cc.) injected intracutaneously merits trial for this purpose.

RABIES

Principle—Active immunity against rabies is produced by the injection of killed or attenuated virus. The usually long incubation period of rabies permits active immunization to be instituted after infection has presumably occurred, and to be completed in time to forestall the development of disease.

Material—Rabic vaccine consists of an emulsion of the brain or spinal cord of a rabbit (or other animal) that has been inoculated with "fixed" rabic virus and allowed to become prostrate with the disease. The animal is then killed, usually on the sixth or seventh day after inoculation. The brain and spinal cord are removed aseptically and treated to decrease or destroy the virulence of the virus.

The *Simple phenolized vaccine* (nonvirulent) is prepared by incubating a homogenized suspension of rabbit's brain in salt solution with 1 per cent phenol. After tests for bacterial sterility and residual virulent virus the preparation is kept refrigerated. For use the vaccine is diluted to contain 4 to 5 per cent of brain tissue, 2 cc. of this dilution being a dose. This is the type of vaccine most available and most commonly employed in the United States of America. Nonvirulent vaccines are also prepared by treatment with other reagents such as ether, formaldehyde and chloroform in much the same manner as the Simple vaccine.

The *Pasteur desiccated-cord vaccine* (virulent) is prepared by drying pieces of the spinal cord of rabbits over potassium hydroxide for from two to four days. After desiccation the cord is placed in glycerol and refrigerated. Three to 4 mm. of cord emulsified in 2 to 3 cc. of water or salt solution constitute a dose.

Recent work* with a dog's brain vaccine, rendered nonvirulent by ultraviolet irradiation, shows it to be a safe immunizing agent, more effective than any of the vaccines in use thus far. As yet it has been used experimentally in dogs only but there is no reason to believe it would prove any less effective in human beings.

Method—With the Simple phenolized vaccine fourteen daily injections.

* Webster L. T. and Casals, J., *Am. J. Pub. Health* 32:268, 1942.

tions of 2 cc usually constitute a course of treatment. In cases with severe bite wounds, especially about the head, seven additional injections are advisable.

Treatment with the Pasteur vaccine consists of sixteen to twenty-five daily injections of vaccine of increasing virulence. The first eight injections use preparations of cord dried four days, the next eight utilize two-day cord, the last nine are usually two- or three-day cord suspensions.

With either preparation the vaccine is administered subcutaneously, usually over the abdomen, the site for each dose being separated as far as possible from that of the previous. A convenient method is to mark off the abdomen into quadrants through the umbilicus, the daily sites being chosen by a clockwise rotation through the quadrants.

Comment—Local treatment of the wound is an essential part of prophylaxis against rabies. Cauterization with nitric acid is an effective and time-honoured procedure. However, recent comparative studies* would indicate that less drastic measures such as thorough cleansing with 20 per cent green soap solution followed by the application of tincture of iodine are probably just as effective. The latter method may well be seriously considered in more superficial bite-wounds especially about the face where the traditional treatment may leave disfiguring scars.

The risk of contracting rabies following the bite of a rabid animal, despite prophylactic immunization, varies from approximately 1 chance in 75 to 1 in 4500 depending on the depth and location of the bite. Wounds on the head are the most dangerous, those on the trunk and legs least so.

The administration of the vaccine (especially attenuated virulent vaccine) is not without a certain risk of its own. The most serious complication of treatment is postvaccinal paralysis, which may be of prolonged duration or even fatal. The incidence of such accidents of treatment is 1 in 3400 with attenuated cord virus and 1 in 8900 to 17,000 with killed vaccines. Paralytic complications seem to be associated with strenuous physical exertion following antirabic prophylaxis, and such patients should be cautioned against undue physical activity. However the treatment should not interfere with the normal daily activities of most people.

(For a comprehensive discussion of the problems of the control of rabies the reader is referred to L. T. Webster's "Rabies," The Macmillan Company, New York, 1942.)

TETANUS

Principle—Active immunity against tetanal toxin is established by the injection of tetanal toxoid.

Material—Toxic filtrates of cultures of *Clostridium tetani* are treated with formaldehyde, yielding tetanal toxoid which lacks the poisonous

* Shaughnessy, H. J. and Zichus, J. J. A. M. A., 125:528, 1943.

properties of tetanal toxin but retains its specific antigenicity. By using "synthetic" or protein-hydrolysate media for growth of the organisms, extraneous inactive protein remaining in the final product can be kept to a minimum. The toxoid may be used in its original fluid state or as a suspension of very slightly soluble alum-precipitated toxoid.

Method—1 Fluid toxoid—Three subcutaneous injections of 1 cc. at three- to four-week intervals constitute an immunizing course.

2 Alum-precipitated toxoid—Two subcutaneous injections of 1 cc. at a two- to three-month interval are required.

With either material a stimulating dose of 1 cc. should be administered after one year. A "booster" dose of 0.5 cc. repeated every spring is probably advisable in children and would undoubtedly maintain a high level of immunity.

In case of an injury involving a risk of tetanal infection 0.5 to 1 cc. of toxoid should be administered subcutaneously. There is evidence that *fluid toxoid* is preferable for such "booster" injections following injury because of a more rapid rise in circulating antitoxin than occurs after the use of alum precipitated toxoid.

Comment—General or even local reactions other than an immediate stinging sensation at the site of injection are rare. Most severe reactions seem to be associated with sensitivity to peptones that may be present in the material used. In persons sensitive to peptones the use of toxoids prepared from peptone-free culture media is essential, in others it is advisable.

Toxoid can be used for antitetanal prophylaxis following injuries *only in persons who have been previously actively immunized. Unimmunized individuals require passive prophylaxis using tetanal antitoxin.*

TYPHOID AND PARATYPHOID FEVERS

Principle—Active antibacterial immunity is produced by the injection of a suspension of dead organisms.

Material—The vaccine should consist of a suspension of a killed smooth strain of *Eberthella typhosa* possessing high virulence, good antigenicity and a complete spectrum of antigenic components. The 42-A-58 strain of the U. S. Army Medical School fulfills these requirements and protects against practically any strain of the typhoid organism that may be encountered. The vaccine is standardized to contain 1000 million organisms per cc.

The triple (TAB) vaccine includes strains of paratyphoid A (*Salmonella paratyphi*) and paratyphoid B (*S. schottmülleri*) that have been chosen to fit the criteria given above. The composition of the triple vaccine is as follows:

Typhoid	1000 million organisms per cc.	
Paratyphoid A	250 "	" "
Paratyphoid B	250 "	" "

Vaccines are also prepared containing larger numbers of the paratyphoid organisms

Method—The vaccine may be administered either subcutaneously or intracutaneously

1 *Primary vaccination* by the standard *subcutaneous* method requires three injections of 0.5, 1 and 1 cc at weekly intervals

By the *intracutaneous* route primary vaccination requires three injections of 0.10, 0.15 and 0.20 cc at weekly intervals

Primary immunization by either method should be carried out two or three months prior to possible exposure to infection

2 *Subsequent or stimulating* ("booster") courses of injections are required after two or three years to maintain immunity (At least one repeat course is mandatory in the Army)

Subcutaneous method Repeat course as outlined above. If practicable one may administer a single dose of 0.5 cc at yearly intervals

Intracutaneous route One intracutaneous injection of 0.10 cc (This is accepted by the Army as a complete secondary or stimulating course) It is preferable to repeat this dose every year if the risk of exposure is high

Comment—The success of the subcutaneous administration of typhoid vaccine is attested by its use in the armed forces in millions of individuals during the past thirty years. Since the institution of compulsory active immunization, typhoid fever has all but disappeared in the armed forces, whereas the incidence of dysentery which is spread in much the same manner has remained at a constant high level over the same period of time

Severe reactions to the use of the vaccine in this manner are uncommon (under 1 per cent of cases) and usually consist of malaise, fever, anorexia, and rarely chills. Local reactions are more common and may give rise to considerable induration, edema and tenderness at the site of injection

The intracutaneous method of administration has not been used in as many cases or over so long a period of time. Recent well-controlled studies indicate that following primary immunization by this method the absolute height of antibody production is not quite as great as with the older method. However, the immunity induced is probably adequate for protection against all but unusually massive infections. This disadvantage as compared to the subcutaneous route may be overcome by increasing the number of injections or lengthening the interval between injections. Reactions of a systemic nature are extremely rare, and local reactions usually consist of a transient induration, erythema, and slight tenderness at the site of inoculation. The method lends itself well to individual as opposed to mass immunization

SCARLET FEVER

Principle—Active antitoxic immunity is produced by the injection of graded doses of scarlatinal erythroxin

Material.—1 The immunizing agent is essentially a filtrate of a broth-culture of scarlatinal hemolytic streptococci. This is then purified to some extent by dialysis and standardized in terms of skin-test doses (STD) For convenience in administration dilutions of 5000 STD per cc. and 50,000 STD per cc. are prepared

2 A relatively insoluble preparation can be made by precipitation of the toxin with tannic acid This is intended for *intracutaneous administration only* and is standardized to contain each of the required doses (750, 3000 and 10 000 STD) in 0.1 cc. An alternative dosage of 500, 2000, 6000 and 10,000 STD per 0.1 cc. is also available

Scarlatinal toxoid has been prepared by treatment of the toxin with formaldehyde, and apparently is a fairly good immunizing agent However, successful detoxification is not regularly accomplished and as yet scarlatinal toxoid is only in the experimental stage. When the technical problems of preparation have been mastered toxoid will undoubtedly be the reagent of choice from the points of view of number of injections required and freedom from reactions following its administration.

Method.—1 *Unmodified Toxin*—A series of graded subcutaneous injections at weekly intervals with a total dosage of 90 to 100,000 STD constitutes an immunizing course. A suggested schedule of dosage is 500, 1500, 3000, 5000, 10,000, 22,500 and 50,000 STD, amounting to 92,500 STD total dosage. With the dilutions mentioned above this consists of 0.1, 0.3, 0.6 cc. of 5000 STD per cc. and 0.1, 0.2, 0.45 and 1 cc. of 50,000 STD per cc. More rapid increases in dosage require fewer injections (five are perhaps the minimum) but entail a high incidence of severe local and often systemic reactions. A longer, more slowly increasing series is often required, especially in adults The Dick reaction is a fairly reliable guide for choice of the initial dose Individuals with markedly positive reactions should receive only 100 to 250 STD as a first dose. Subsequent doses are gauged by the reaction to the preceding dose.

A Dick test should be performed one week after the last dose. If it is still positive an additional injection of 50,000 STD usually suffices to convert the Dick reaction to negative.

2 *Tannic Acid Precipitated Toxin*—In children three *intracutaneous* injections of 750, 3000 and 10 000 STD (in 0.1 cc.) at two week intervals constitute a course.

In adults four intracutaneous injections of 500 2000, 6000 and 10,000 STD (in 0.1 cc.) at two-week intervals are suggested

Immunity may be tested three to four weeks after the last injection by means of the Dick test If still positive a supplementary dose of 10 000 STD intracutaneously usually suffices to establish immunity

Comment—Any schedule of dosage should be considered as purely

tentative and subject to modification, depending on the reactions of the individual being immunized Slavish adherence to printed schedules negates the basic principle of individualization of treatment, and particularly in the case of scarlatinal prophylaxis has done much to discredit its use because of the uncomfortable and severe reactions that follow ill-advised dosage schedules

The immunity produced by this procedure is *purely antitoxic* in nature and not directed against the streptococcus proper Nevertheless, infections with scarlatinal streptococci in Dick-negative individuals rarely result in mastoiditis, suppurative lymph nodes, nephritism or cardiac involvement—complications that are so common in unmodified scarlet fever One may say that in scarlet fever immunity to one aggressive weapon of the streptococcus is far better than no immunity at all Sulfonamides have proved of tremendous value in the therapy of streptococcal infections, but one must not forget that they have no action against the toxic phase of the disease

SMALLPOX

Principle—Active immunity against variola is induced by inoculation with a live virus of a related disease (vaccinia)

Material—Vaccine virus consists of a homogenized glycerolated suspension of vesicular material from a calf that has been inoculated with vaccinia After a “ripening” interval the vaccine is tested for potency and for the presence of anaerobic and virulent aerobic contaminants Although absolute bacterial sterility is rarely achieved, the number of viable bacteria, chiefly nonvirulent staphylococci, is kept to a minimum by the addition of 0.5 per cent of phenol The vaccine is packaged in sealed capillaries containing sufficient material for one immunization The virus is very sensitive to heat and *must be kept continuously refrigerated, preferably below freezing*, until used The freezing compartment of mechanical refrigerators is ideal for the storage of vaccinal virus

Bacterially sterile virus can be produced by growth on chick embryos However, such cultural methods result in the loss by the virus of some component essential for producing complete immunity in man and other mammals Until this deficiency can be corrected by improved cultural methods, the traditional calf vaccine remains the agent of choice

Method—The site of vaccination is prepared by thorough cleansing with soap and water, followed by a volatile antiseptic such as ether, acetone or undenatured 95 per cent alcohol, which is allowed to dry Under no circumstances should a nonvolatile disinfectant such as iodine, organic mercurials (mercurochrome, metaphen, merthiolate) or even denatured alcohol be used in the preparation of the site as the virus is readily inactivated by such reagents resulting in the failure of the vaccination to “take.”

The capillary container having been wiped with ether or acetone, both ends are broken off and the vaccine expressed onto the skin by means of a bulb supplied with the material. The skin is held taut with one hand and firm pressure is applied through the drop of vaccine with the side of the point of a sterile ordinary needle held parallel to the skin surface. Twenty to thirty such strokes over an area not exceeding $\frac{1}{4}$ inch in diameter suffice to introduce an adequate amount of virus. The pressure of application of the needle should produce a barely visible abrasion and should not draw blood.

After vaccination the excess material may be wiped off gently with sterile gauze. No dressing is required. Under no circumstances should a "vaccination-shield" be worn. In children the site may be protected with dry sterile gauze for one or two days to prevent secondary vaccinia due to contamination of the fingers with active virus.

Comment—The skin over the insertion of the deltoid muscle is the site of choice for vaccination. Many individuals request vaccination at other presumably less conspicuous sites, such as the thigh, for alleged esthetic reasons. Secondary infection of the vaccination is much more common in such sites, and because of the tenseness of the surrounding tissues primary "takes" are much more painful and temporarily disabling than when performed on the upper arm. The scar following a properly performed vaccination is barely visible, forming what has been called a "sanitary dimple," and should hardly be objectionable to the most fastidious esthete.

Three possible reactions may follow successful inoculation with a potent vaccine. By observations two, four and eight days after vaccination these may be identified:

- 1 *Primary vaccinia*, in people who have not been previously vaccinated (who have not had smallpox) or who have lost all immunity conferred previously. A small papule appears on the third to fifth day, becoming a vesicle, and developing into a characteristic umbilicated pustule at the height of reaction by the eighth to tenth day. A dark, dry, crust then forms, falling off after one or two weeks to leave an inconspicuous foveated scar.
- 2 *Vaccinoid reaction*, in people who possess some but not complete immunity. The course of events is similar to a primary "take" but at an accelerated rate, the height of reaction being reached in four to seven days.
- 3 *Reaction of immunity*, in people who possess complete immunity. A small, often itchy, reddened area of induration appears within one day, often as soon as eight hours, enlarges somewhat to a maximum in twenty-four to forty-eight hours, and disappears, leaving no scar. Occasionally a minute vesicle may be present at the height of the reaction.

It is seen, thus, that vaccination serves as a test of immunity to smallpox. As a test procedure it is unique in that in people who show no immunity it automatically remedies the defect. Primary vaccination should be performed in the first year of life, and the state of immunity tested by revaccination on entering primary school and high school and at intervals thereafter. Smallpox can be eradicated only by such a program of vaccination and revaccination of the entire population.

In persons with eczema or similar disseminated skin lesions vaccination is best postponed until the skin returns to normal, as generalized vaccinia may follow inoculation. However, *in the face of an epidemic or other likely exposure to smallpox there are no contraindications to vaccination.*

COMBINED IMMUNIZATION

Simultaneous immunization against more than one disease, using combined antigens, offers certain advantages. The saving in time and the smaller number of injections required are immediately apparent. Moreover there is considerable evidence that the immune response to such combined antigens is often greater against each than when separate inoculations are used. The reactions following administration of mixed preparations are not appreciably greater than those following the usual single antigens (especially in children) and they lend themselves particularly well to routine prophylaxis in pediatric practice. There are at present available a variety of mixtures for such combined immunization. The most widely used of these are

Diphtheric and tetanal toxoids combined

Diphtheric toxoid and pertussis vaccine combined

Diphtheric and tetanal toxoids and pertussis vaccine combined

Tetanal toxoid and typhoid vaccine combined

As an exception, smallpox vaccination which involves the introduction into the body of a live dermatropic virus should preferably be performed alone. Any injury to the skin (even the insertion of a needle) may result in secondary vaccinia at the site of the injury. To guard against such complications, though the risk is perhaps small, other inoculations were best postponed until the height of the vaccinal reaction has passed.

CONDUCTIVE DEAFNESS AND ITS RELATION TO LYMPHOID HYPERPLASIA OF THE NASOPHARYNX

Benefits from X-ray Therapy

EDWARD B D NEUHAUSER, M D * AND CHARLES F FERGUSON, M.D †

ONE of the most important phases of preventive medicine in pediatrics concerns the early recognition and the prompt and proper treatment of children with impairment of hearing. During recent years it has become increasingly apparent that most of the cases of chronic progressive deafness in adults have resulted from unrecognized and untreated defects dating back to childhood. Had these defects been properly treated in their earlier stages before irreversible reactions had occurred, many individuals who are thus so severely handicapped to-day would otherwise be living normal lives.

Crowe and Baylor¹ have stated that if children in the primary grades of school were given yearly nasopharyngoscopic examinations, and that if proper treatment by radiation of discovered hyperplastic lymphoid tissue were carried out, in the next generation there would be a 50 per cent reduction of adult cases of deafness. When one considers that at the present time in the United States alone there are approximately 15 000,000 deaf or partially deaf individuals, it becomes obvious that by adequate treatment a tremendous number of such individuals could be rescued from a life-long crippling impairment.

Until recent years, when deafness in childhood has been suspected, the only satisfactory treatment at hand was surgical removal of the tonsils and adenoid. This was often performed with very encouraging and often dramatic results, but unfortunately many of these children again developed increasing impairment of hearing which was very often not relieved by secondary adenoidectomy. Many more cases of deafness are being discovered today because of the increased use of the audiometer in schools, clinics, hospitals and physicians' offices. The high incidence of this disease is now just beginning to be appreciated. In 1938 Crowe and Guild² made the revolutionary statement that high tone impairment which previously had always been considered the result of a lesion of the cochlea or of the auditory nerve was in reality often the earliest sign of conductive deafness on the basis of partial occlusion of the eustachian orifices by hyperplastic lymphoid tissue.

From the Infants and Children's Hospitals of Boston.

* Instructor in Radiology, Harvard Medical School; Roentgenologist, The Infants and Children's Hospitals of Boston; Roentgenologist, Boston Lying in Hospital.

† Assistant in Otolaryngology, Harvard Medical School. Associate Visiting Otolaryngologist, The Infants and Children's Hospitals of Boston.

Today this has been established as a well-known fact. In such cases the bone conduction may be reduced as well, even before there is much loss of low tones—a phenomenon also previously considered due to nerve deafness. The restoration of adequate ventilation of the middle ear by re-establishing patency of the eustachian tubes often results in a rapid return to normal hearing. This finding is easily demonstrated by the audiometer and tuning fork test. For this reason, many patients who previously had been classified as having a nerve deafness for which there was no satisfactory treatment, now fall into the category of treatable cases with good promise for restoration of normal hearing.

According to Crowe and Burnam,³ 75 per cent of children who have had adenoidectomy performed before puberty have visible evidence of recurrence of such lymphoid tissue. The lymphoid nodules are an integral part of the mucosa of the pharynx and nasopharynx, and cannot be completely removed by surgery in any case. After the excision of the large mass of adenoid or tonsillar tissue, the small lymphoid follicles tend to hypertrophy, thereby producing the clinical appearance of "granular" pharyngitis or nasopharyngitis. Many of these nodules are in the region of the eustachian orifices or in the actual pharyngeal portion of the eustachian tubes—obviously inaccessible to surgical means. An increase of this tissue as a result either of infection, normal physiologic hypertrophy with growth, or as a response to surgical removal of masses of such tissue will produce partial occlusion of the tube with a resulting chronic tubotympanic catarrh. If left untreated, irreversible changes are produced in the middle ear which result in permanent catarrhal deafness for which there is no adequate treatment. After the age of fifteen years treatment is much less satisfactory because these secondary changes in the middle ear and tube may be so advanced. Therefore, treatment of the lymphoid tissue must be undertaken in childhood before these irreversible changes have occurred. This present discussion concerns the use of some form of radiation to destroy the lymphoid follicles and their lymphocytes.

It has long been known that lymphoid tissue is unusually sensitive to x-radiation and radium and for this reason can be inhibited by very small doses of these agents. The lymphocyte has a definite life cycle just as have cells of the skin, and the old lymphocytes progress outward into the crypts and are phagocytized, with new ones taking their places. Radiation prevents cell division and formation of new lymphocytes (Crowe and Baylor¹). The germinal centers of the follicles are injured and obliterative changes of the endothelium of both blood vessels and lymphatics are produced (Schenck⁴). The amount of radiation is not sufficient to cause dryness or atrophy of the mucous membrane, it does not cause crusting in the mouth, pharynx or nasopharynx, it produces no skin changes, involvement of the pituitary or other untoward reactions. Repeated treatment, however, may be necessary to hold this tissue in check during the years of active pro-

liferation of lymphoid tissue until adolescence is reached. If adolescence is reached and the eustachian tubes and orifices have been kept patent, the hearing should then remain normal, without necessity for continued treatment in adult life. If this is not done, treatment in adult life will be of no value.

DIAGNOSIS

In any patient suspected of deafness, the first essential is a complete history. This includes a family history to determine whether deafness in other members of the family has occurred in early life. Familial deafness in early life makes one very suspicious of otosclerosis, which gives a clinical picture of conductive deafness, yet is not helped by radiation. Certain types of congenital deafness also occur in families. The history should also include questions as to serious illnesses such as pneumonia, meningitis, scarlet fever, head injuries, or other factors which might produce a cochlear or nerve lesion.

A complete physical examination also should be done, and this should include a very complete examination of the ear, nose and throat. Nasopharyngoscopy should be performed on all such patients even if the small children may require a general anesthetic for the procedure. Only by direct observation of the nasopharynx can the location of the lymphoid tissue be accurately determined and its relation to the eustachian orifices be ascertained. A large midline mass of adenoid tissue may have no obstructing effect upon the eustachian tubes, whereas a clean vault with hyperplastic nodules around the lips of the tube may produce a very severe type of conductive deafness. Examination of the ears with the aural speculum usually will show retraction of the drums due to closure of the tubes with absorption of contained air. Retraction of the drums produces an increased prominence of the short process and handle of the malleus, with foreshortening of the handle and a diffused light reflex. Shrapnell's membrane is often markedly retracted. In cases of long-standing catarrhal deafness, there may be considerable thickening and dullness of the drums.

The voice tests, including the whispered and spoken voice, will show definite diminution of hearing. Tuning fork tests in conductive deafness will usually show the Weber test (a vibrating tuning fork placed in the center of the head) lateralized to the deaf ear, whereas in nerve deafness the Weber test is usually lateralized to the good ear. The Rinne test (performed by placing a tuning fork over the mastoid process until the instant at which the vibration is no longer perceptible and then replacing it in front of the auditory canal) in the normal ear will give an air conduction in seconds of approximately twice that by the bone conduction. This same ratio is often maintained in nerve deafness even though the air and bone conduction are both decidedly reduced. In the typical conductive deafness, the Rinne test may be reversed so that the bone conduction, although in itself pos-

sibly somewhat diminished, is more prolonged than the air conduction. It is best to use a tuning fork of 256 or 512 frequency, as lower pitched forks will produce too much vibratory sensation as well as sound. These tests should be supplemented by carefully performed audiometer tests. The curve of conductive deafness may be generally depressed throughout all tones, or it may be a low tone deafness with fairly good high tones. As mentioned above, many cases, however, show fairly normal low tones with fairly normal mid tones, but a marked falling off of the higher tones, even though there is no nerve involvement. An abrupt drop in any curve paralleled by a similar marked drop in bone conduction usually suggests a lesion of the cochlea or the nerve. In these cases, radiation is useless.

In the average child under four to five years of age, audiometric studies and tuning fork tests are quite unreliable, as considerable concentration and cooperation are necessary for proper evaluation of these tests. In such cases the word of the parent or kindergarten teacher is of great importance as far as the possibility of an existing deafness is concerned. Examination in a strange office may be rather frightening to the apprehensive patient, whereas the mother will know that at home the child cannot hear the radio unless it is very loud and cannot hear family discussions which undoubtedly would otherwise interest him. In such cases, investigation of the nasopharynx is just as important as if audiograms had shown typical conductive deafness curves.

TREATMENT

When the diagnosis of conductive deafness due to hyperplastic lymphoid tissue in the nasopharynx has been established, a decision as to the use of surgery or radiation must be made. If there is a sizable mass of adenoid tissue, it is usually best to remove it surgically. If this has already been done, it should be noted whether secondary hypertrophy of lymphoid follicles has occurred. If any of this tissue is present in or about the eustachian orifices where curettage would be impossible or dangerous because of the possibility of producing stenosis of the orifices, then radiation is advisable. Radon applied directly to the nasopharynx has been used in recent years with complete success (Crowe and Burnam,³ Burnam⁵). Since 1939 we have been employing γ -radiation with equal success, and the efficacy of this form of treatment has been confirmed by other clinics and investigators (Rentschler and Settle,⁶ Caruthers⁷). X-ray therapy has several obvious advantages over the use of radium or radon. The necessary equipment is usually available in the smaller communities and hospitals as well as in the larger centers, and little skill or experience is required to obtain a completely satisfactory response, and sedation or anesthesia usually is not necessary.

Thirty-eight patients with conductive deafness have been treated

at the Children's Hospital by x-radiation, but only sixteen have had completely satisfactory follow-ups. In two patients the response was

A

B

Fig 177—Audiograms showing the status of hearing in a patient, A, before and B after x ray therapy (Courtesy of Maico Acoustic Instrument Co., Minneapolis, Minn)

not satisfactory. One of these had nerve deafness and was advised only with a vague possibility of improvement. The

twelve showed an excellent response as seen by accompanying table. Typical audiograms of two patients are shown in Figures 177 and 178.

When at the Children's Hospital we first began x-ray treatment of hyperplastic lymphoid tissue, there was considerable variation in the amount of radiation administered and in the number of treatments given. It was our final decision that 800 r measured in air was sufficient to restore the patency of the eustachian orifices and at the present time it is our custom to treat through two lateral ports sufficiently large to cover the nasopharynx, 6 x 8 cm is usually adequate. At one sitting 200 r is given through each lateral port with the following factors 200 KV, 10 MA., 50 cm T.S.D., 10 mm. Al, and 0.5 mm Cu filtration with a HVL of 1.05 mm. of copper. One week later a similar treatment is given and the patient is asked to return in six weeks.

for reevaluation and a recording by the audiometer. There have been no unpleasant reactions except that a small percentage of the patients will complain of fullness in the parotid region and show slight swelling of each parotid gland. The patient's family is warned that this may occur within twelve hours after the treatment, but will subside rapidly if an ice bag is applied locally. A few grains of aspirin will control local discomfort due to the swelling.

The importance of the early recognition of conductive deafness and the immediate institution of adequate treatment cannot be overemphasized. It does not appear material whether radium, radon or x-radiation be employed so long as treatment is complete. We recommend

without hesitation the use of x-radiation because of the simplicity of treatment and because of its general availability. We feel that the response has been completely satisfactory, and that if radiation methods were more generally employed, many thousands of cases of permanent, partial or complete deafness could be obviated.

SUMMARY

The importance of the early recognition of conductive deafness due to excessive lymphoid tissue in the nasopharynx with blockage of the eustachian tubes has been emphasized.

The criteria for establishing the diagnosis have been elaborated, and the importance of careful audiometer tests has been discussed.

The treatment of this condition by means of roentgen therapy following primary adenoidectomy offers a simple and effective method of controlling most cases of conductive deafness in childhood. X-ray therapy should be available in all hospitals and should be more widely employed.

THE TREATMENT OF MENINGITIS

JOHN A. V. DAVIES, M D

THE treatment of the common forms of meningitis caused by pyogenic bacteria has, with one or two exceptions, progressed rapidly in recent years. We owe this progress largely to the development and application of specific antisera and the chemotherapeutic agents, the sulfonamides and penicillin. Measured in terms of decreasing mortality, there is cause for great satisfaction over the results. Analysis of the survivors in terms of their neurologic state reveals how much remains to be done in order to avoid irreparable damage to the central nervous system.

In the past fifteen years at least 864 patients were treated at the Infants and Children's Hospital of Boston for meningitis due to pyogenic bacteria. The causative organisms were as follows:

Organisms	No. of Cases
Meningococcus	214
Hemophilus influenzae	190
Mycobacterium tuberculosis	153
Pneumococcus	150
Streptococcus	105
Staphylococcus aureus	31
Endamoeba coli	17
Miscellaneous (Serratia, Proteus, Alcaligenes, Paratyphoid, one each)	4

Age Incidence—The incidence of meningitis reaches its peak in infancy. During epidemic years of meningococcal meningitis, children and adults may be attacked in large numbers, but infants retain their unenviable lead. Their lack of resistance to infections in general, their metabolic instability, and the practical difficulties of handling infants and administering treatments enable one to assert that if infants can be cured, treatment of adults will be relatively easy. The fact that injury to the growing nervous system projects itself far ahead, perhaps in a widening arc, into adult life, adds to the responsibility of the physician in charge of these patients.

PREVENTION

A discussion of the treatment of meningitis naturally extends to methods of prevention. Public health measures involving better homes and medical care, avoidance of overcrowding, supervision of school children, separation of the sick from other members of the household, and reduction in the incidence of respiratory infections in general should have a beneficial effect on the incidence of most types of men-

ingitis Prompt recognition and treatment of foci of infection elsewhere in the body may prevent direct or hematogenous extension of the organisms to the meninges

In the case of tuberculous meningitis, which still has a mortality of almost 100 per cent, the above measures are of paramount importance Pending the development of specific remedies, on which a great deal of work is now being done, one can only hope that tuberculosis will be wiped out completely by public health measures

More specific remedies are available to individuals intimately exposed to meningococcic infection Even a small dose of one of the sulfonamides in common use, over a period of three or four days, may be justified One dose of 2 gm of sulfadiazine, for example, is usually sufficient to suppress meningococci in the nasopharynx of adult carriers Institutions faced with an epidemic of meningococcic meningitis may wish to administer a small daily dose of a suitable sulfonamide such as sulfadiazine (approximately one-third to one-fourth the usual therapeutic dose) to its members, as long as the hazard exists

DIAGNOSIS

Now that effective therapeutic tools are at hand, the early diagnosis of meningitis is of more than academic importance The sooner these tools are brought to bear on the patient's illness, the better are his or her chances of survival with an intact central nervous system

Clinical Signs and Symptoms—The infrequency of meningitis in general practice serves to catch many physicians by surprise, even when the cardinal symptoms and signs, such as fever, headache, nausea, vomiting, stiff neck and back, and a positive Kernig clearly present themselves In infants it is too often the mother who first notices the bulging of the anterior fontanel Inasmuch as meningitis is commonest in infancy it is worth while to emphasize that a bulging fontanel is a prime indication for a diagnostic lumbar puncture Other evidence of meningitis may be equivocal or misleading Often there is a history of a respiratory infection from which the infant is apparently recovering when he has a return of fever and becomes irritable or listless and refuses feedings or vomits repeatedly The patient may be unresponsive Convulsions and twitching of the face or extremities may set in Stiffness of the neck and a positive Kernig sign may be elicited On the other hand, the infant may be in a state of shock, with a subnormal temperature and a normal or low white blood count The anterior fontanel may even be depressed and the patient limp and exhibit no stiffness of the neck So uncertain and variable are the signs of meningitis in this age group that one should perform a lumbar puncture in every case when a reasonable *suspicion* of meningitis exists

Laboratory Examinations—After the history and physical examination, the timing of the procedures will depend on the judgment of the physician in charge Usually the order is as follows

1 *Blood culture and blood count* A blood culture is of value as an indication of the extent of the infection. A positive blood culture offers confirmatory evidence of the type of infection in the meninges. At least one flask should be incubated at partial tension of oxygen.

Urinályses and blood counts should be repeated every two or three days if a sulfonamide is given.

2 *Nasopharyngeal culture*

3 *Lumbar puncture* When an infant is involved, some prefer to hold the patient in a sitting position reclining forward against a firm pillow. A good assistant, who can minimize movement by the patient, is very important. A short-beveled No. 21 needle may be used for infants, depending somewhat on the wishes of the operator. A smaller bore is more easily clogged with fibrin. If the optic disks are choked, an intracranial tumor must be considered. In any case, the lumbar puncture should be performed with caution, lest the brain stem herniate into the foramen magnum.

4 *Urinálalysis*

5 *Laboratory consultation and assistance* The original specimen of spinal fluid should be cultured on ordinary blood agar and on chocolate agar slants. It is customary to allow 5 to 10 drops of spinal fluid to drop directly upon two chocolate agar slants and to incubate one at partial tension of carbon dioxide in, for example, a "candle jar." Additional fluid is taken in one or two sterile test tubes for inoculation of a blood agar plate (the more easily to identify beta hemolytic streptococci) and for a total and a differential cell count (with Wright's stain or methylene blue), a globulin test, a total protein determination (if desired), sugar determinations, and a direct smear.

When organisms are found on smear of the original fluid (centrifuged, if the organisms are scarce) steps should be taken at once to identify them as quickly as possible. If gram negative biscuit-shaped diplococci are seen their relative number and the presence or absence of phagocytosis should be noted as prognostic aids. It is customary to type meningococci. Strangely enough, even experienced physicians may occasionally have difficulty in decolorizing meningococci stained by Gram's method and may confuse them with gram positive cocci. Because of its pleomorphism, *Hemophilus influenzae* is often missed entirely or confused with *Escherichia coli* or the meningococcus.

If organisms resembling *Hemophilus influenzae* or pneumococci are seen on smear a determined effort should be made to type them at once by the Neufeld method of capsular swelling. If *H. influenzae* is suspected but the common strain B is not found the organisms may belong to the less virulent respiratory strain for which antiserum is unnecessary or to one of the other five smooth strains. Type F is occasionally encountered and for this a small amount of antiserum has been developed. Organisms too scarce for immediate typing may be incubated either in the original spinal fluid or in Fildes' broth for four to eight hours and then concentrated by centrifugation at about 2500 r.p.m. for fifteen minutes. The same rule applies to pneumococci which may be grown in broth enriched by serum or blood or in ascitic fluid. In typical cases, pneumococci are present in large numbers in the original spinal fluid.

Organisms found in the original culture should be saved for possible future needs, such as tests of susceptibility to the chemotherapeutic agents employed

Spinal fluid sugar determinations may be made in the chemical laboratory or by a rough estimation in the clinical laboratory. If 1, 2, 3, 4 and 5 drops of spinal fluid (from a 1 cc. pipette) are mixed respectively with the contents of five small test tubes, each containing 1 cc. of Benedict's qualitative reagent, and heated in boiling water for five minutes, the presence or absence of even a slight reduction at the end of this time indicates the presence of sugar. One or two drops of normal spinal fluid will usually cause some reduction. In purulent meningitis, the tubes may all remain blue as long as the infection is active. Normal spinal fluid usually contains 60 mg or more of dextrose per 100 cc., provided the blood sugar level is normal.

Alexander has worked out a somewhat more accurate table, as follows

Tube Number	Cerebro-spinal Fluid Added	Reduction of Benedict's Solution					
		+	0	0	0	0	0
1	0.05 cc.	+	0	0	0	0	0
2	0.1 cc.	+	+	0	0	0	0
3	0.15 cc.	+	+	+	0	0	0
4	0.2 cc.	+	+	+	+	0	0
5	0.25 cc.	+	+	+	+	+	0
		Over	40 to	30 to	20 to	10 to	10
Mg of dextrose per 100 cc		50	50	40	30	20	10

Virus infections of the meninges are characterized by a tendency toward a lymphocytic cellular response in the cerebrospinal fluid, by a normal sugar content, negative smears and sterile cultures

Whenever *tuberculous meningitis* is suspected, a tuberculin skin test, using a 1:10,000 dilution of Old Tuberculin or one comparable to this of another preparation, should be done at once. If this is negative, proceed with stronger dilutions, up to 0.1 cc. of 1:10 dilution Old Tuberculin. The spinal fluid may be examined by staining the centrifuged sediment or the web which forms for acid-fast bacilli enmeshed in the web. painstaking search on more than one occasion for a total of several hours is usually necessary. Culture and guinea pig inoculation with the centrifuged sediment may provide the only proof of tuberculous meningitis. Anxious relatives and friends press one for an early diagnosis

TREATMENT

Supportive Measures—In fulminating or neglected infections, supportive measures may be life-saving and should at times take precedence over diagnostic and specific therapeutic measures. These include the administration of oxygen (tent, cone or nasal catheter), ether, other intravenous or subcutaneous sedatives to control convulsions, and above all, fluids. If there is evidence of dehydration or a history of persistent vomiting or inanition, intravenous fluids, such as 5 or 10 per cent dextrose in water (10 cc per pound of body weight), followed by a hypodermoclysis of physiological saline solution (10 cc per pound of body weight), are indicated. A continuous intravenous drip, to supply 10 cc per pound per hour, may be advantageous in the more severe cases. When an infant shows evidence of acute cerebral edema, 10 to 20 cc of 50 per cent dextrose solution intravenously may give temporary benefit. In milder infections, diagnostic and spe-

cific therapeutic measures come first but sulfonamides should not be given until the patient has been well hydrated, lest insoluble crystals obstruct the renal tubules. Adequate fluids are probably of greater value than alkalization of the urine in preventing hematuria or anuria.

Other foci of infection should be eradicated whenever possible. They may respond to medical care or they may require surgical interference. The indications for surgery are the usual ones, but in the parameningeal infections—sinusitis, otitis media, mastoiditis, and osteomyelitis of the skull—in case of doubt one should probably operate.

Specific Treatment—Specific *antisera*, when given, should be preceded by careful tests for hypersensitivity. Antiserum should not be used for this purpose, lest an antigen antibody reaction in the eye or skin cause a false positive reaction and unnecessarily delay the administration of therapeutic serum. A syringe of adrenalin chloride 1:1000, containing 0.3 to 0.5 cc. should be ready. Antiserum may be given intravenously, slowly, undiluted, or in normal saline by slow infusion or drip so that the full dose is given within two hours. Serum may also be given intramuscularly or half by this route and half intravenously. The intramuscular route is probably less efficient and calls for a larger dose of antiserum.

Adequacy of dosage is determined above all by the clinical condition of the patient and the spinal fluid findings. It is desirable to test the patient's own serum for specific antibodies twelve to twenty-four hours after the administration of therapeutic serum, and at least every other day thereafter until convalescence is definitely established. Practice varies, some clinics requiring demonstrable antibodies in a 1:10 dilution of the patient's serum. Others assay the level in undiluted serum. In severe infections a greater excess of antibody is probably called for but patients have recovered whose own serum, tested by its ability to cause capsular swelling of the specific organism (Neufeld reaction), contained no demonstrable antibodies. Blood for this assay may be collected in capillary tubes after finger puncture.

When horse antiserum has been used, capsular swelling may not appear even with excess of antibody as determined by agglutinins or mouse protection. Furthermore, the Francis intradermal test for a positive balance of pneumococcus antibodies and the comparable Dingle test for H. influenzae are less reliable with horse antiserum.

If the infection is stubborn and specific antibodies are no longer demonstrable in the blood stream, it may be necessary to repeat the injection of antiserum, preferably within the first week, lest the patient become hypersensitive to this serum.

Sulfadiazine is in most instances the sulfonamide of choice because of its wide bacterial coverage and the fact that what toxic effects it may exhibit do not as a rule cause nervous symptoms which might confuse the picture. It penetrates the blood brain barrier fairly well, although this characteristic may not be of prime importance.

The finding of a predominance of polymorphonuclears and reduced sugar in the initial spinal fluid specimen, even if organisms are not visible on smear, calls for sulfadiazine, pending an exact diagnosis of the causative agent

The route of administration varies. In mild cases of meningitis it may be given orally, but it is probably wise to give at least the first two doses as the sodium salt either intravenously or subcutaneously (up to 5 per cent saline)

The first dose is 0.1 gm per kilogram of body weight (or $\frac{2}{8}$ gram per pound). This or a larger or smaller dose should be repeated in eight or twelve hours, *depending on the blood level*. Except in the case of meningococcal infections, which respond somewhat more readily than do the other forms, a blood level of at least 10 to 15 mg per 100 cc is desirable until the infection has subsided. Some clinics advocate even higher blood levels. As mentioned previously, an adequate intake of fluids is imperative in order to reduce the likelihood of renal complications.

As soon as the patient can swallow sulfadiazine and retain it, the drug may be given orally in divided doses ranging from 0.15 to 0.3 gm per kilogram of body weight (1 to 2 grains per pound) per day, depending on the blood level desired.

Penicillin, when indicated, should be given intramuscularly for at least one week. It should be given intrathecally also for at least five days after the spinal fluid becomes sterile. When the response is slow or there is evidence of localized infection, a longer course should be adopted. Intrathecally it may be injected in concentrations of 1000 to 5000 units per cubic centimeter of physiologic saline, after spinal fluid has been withdrawn. In no case should a greater volume of fluid be injected than was withdrawn. The present trend is toward larger doses. Infants should probably receive 10,000 units twice a day and children and adults at least double this amount, in order to maintain a spinal fluid level of 0.05 Oxford units or more per cubic centimeter at all times.

A localized pocket of infection within the skull, when accessible, should be drained. Should the ventricles contain pus which cannot be drained off by lumbar or cisternal puncture, they may be irrigated with normal saline or Ringer's solution by means of suitable needles inserted through the lateral angles of the anterior fontanel or through burr holes. Penicillin, if indicated by the organism found, is then injected into the ventricles.

Lumbar Puncture—So much importance is rightfully attached to the lumbar puncture that a summary of the indications for this procedure may be of value.

1 *Diagnostic*—If the first spinal fluid obtained is normal but the condition still suggests the diagnosis of meningitis, the lumbar puncture should be repeated. If no fluid is obtained, after repeated trial at more

than one level, a cisternal puncture should be done. Failing this, sub-arachnoid or ventricular puncture may be carried out through the lateral angles of the anterior fontanel of infants or through burr holes in the parietal regions of the skull. Naturally, only those familiar with the required technic should attempt these latter procedures, and the indications must be well established.

2 *The Relief of Intracranial Pressure*—Prolonged high pressure may damage sensitive brain cells irreparably. The ideal arrangement would permit continuous removal of excess cerebrospinal fluid, perhaps by an indwelling spinal needle or small catheter. The restlessness of patients and the accumulation of fibrin are inimical to the success of this device.

During the early stages of treatment, before the inflammation within the meninges has subsided, frequent lumbar punctures may be necessary as long as the pressure at the previous puncture is high or whenever the anterior fontanel bulges or vomiting or headache continues.

The subtotal replacement of cerebrospinal fluid and the inflammatory products of the infection—fibrin and pus as well as the soluble specific capsular carbohydrate of such organisms as *H. influenzae* and pneumococci—by oxygen (or air) early in the course of treatment has some justification and is worthy of careful trial in the more resistant forms of meningitis. The technic is that of a pneumoencephalogram. Oxygen is to be preferred, since it is more rapidly absorbed, giving way to fresh spinal fluid. Late in the course of the disease this procedure would seem to offer very little. Although in our hands this treatment has not caused exitus, it is followed by some symptoms of shock and should be reserved for those forms of meningitis relatively resistant to available therapy.

3 *Intrathecal Treatment*—The Infants' and Children's Hospitals of Boston were among the first to discontinue the administration of intrathecal serum, because of its tendency to increase the inflammatory reaction and thereby promote adhesions and the pocketing of pus within the subarachnoid space. The rare exceptions to this rule will be taken up later.

Penicillin, unlike the sulfonamides, is not inhibited by pus and causes very little reaction when injected intrathecally. The blood-brain barrier serves to keep it out of the subarachnoid space even when there is a good blood level. On the other hand, it disappears within one or two days (depending on the individual case) from the subarachnoid space, and must be reinjected intrathecally at intervals of twelve to twenty-four hours for maximum effectiveness. Except in mild infection, a spinal fluid level of penicillin should be determined daily during the infection.

in the presence of heparin (or a comparable anticoagulant) more in normal saline every twenty-four hours. These methods have theoretical advantages in the di-

The finding of a predominance of polymorphonuclears and reduced sugar in the initial spinal fluid specimen, even if organisms are not visible on smear, calls for sulfadiazine, pending an exact diagnosis of the causative agent

The route of administration varies. In mild cases of meningitis it may be given orally, but it is probably wise to give at least the first two doses as the sodium salt either intravenously or subcutaneously (up to 5 per cent saline)

The first dose is 0.1 gm per kilogram of body weight (or $\frac{3}{8}$ grain per pound). This or a larger or smaller dose should be repeated in eight or twelve hours, *depending on the blood level*. Except in the case of meningococcal infections, which respond somewhat more readily than do the other forms, a blood level of at least 10 to 15 mg per 100 cc is desirable until the infection has subsided. Some clinics advocate even higher blood levels. As mentioned previously, an adequate intake of fluids is imperative in order to reduce the likelihood of renal complications.

As soon as the patient can swallow sulfadiazine and retain it, the drug may be given orally in divided doses ranging from 0.15 to 0.3 gm per kilogram of body weight (1 to 2 grains per pound) per day, depending on the blood level desired.

Penicillin, when indicated, should be given intramuscularly for at least one week. It should be given intrathecally also for at least five days after the spinal fluid becomes sterile. When the response is slow or there is evidence of localized infection, a longer course should be adopted. Intrathecally it may be injected in concentrations of 1000 to 5000 units per cubic centimeter of physiologic saline, after spinal fluid has been withdrawn. In no case should a greater volume of fluid be injected than was withdrawn. The present trend is toward larger doses. Infants should probably receive 10,000 units twice a day and children and adults at least double this amount, in order to maintain a spinal fluid level of 0.05 Oxford units or more per cubic centimeter at all times.

A localized pocket of infection within the skull, when accessible, should be drained. Should the ventricles contain pus which cannot be drained off by lumbar or cisternal puncture, they may be irrigated with normal saline or Ringer's solution by means of suitable needles inserted through the lateral angles of the anterior fontanel or through burr holes. Penicillin, if indicated by the organism found, is then injected into the ventricles.

Lumbar Puncture—So much importance is rightfully attached to the lumbar puncture that a summary of the indications for this procedure may be of value.

1 *Diagnostic*—If the first spinal fluid obtained is normal but the condition still suggests the diagnosis of meningitis, the lumbar puncture should be repeated. If no fluid is obtained, after repeated trial at more

than one level, a cisternal puncture should be done. Failing this, sub-arachnoid or ventricular puncture may be carried out through the lateral angles of the anterior fontanel of infants or through burr holes in the parietal regions of the skull. Naturally, only those familiar with the required technic should attempt these latter procedures, and the indications must be well established.

2 *The Relief of Intracranial Pressure*—Prolonged high pressure may damage sensitive brain cells irreparably. The ideal arrangement would permit continuous removal of excess cerebrospinal fluid, perhaps by an indwelling spinal needle or small catheter. The restlessness of patients and the accumulation of fibrin are inimical to the success of this device.

During the early stages of treatment, before the inflammation within the meninges has subsided, frequent lumbar punctures may be necessary as long as the pressure at the previous puncture is high or whenever the anterior fontanel bulges or vomiting or headache continues.

The subtotal replacement of cerebrospinal fluid and the inflammatory products of the infection—fibrin and pus as well as the soluble specific capsular carbohydrate of such organisms as *H. influenzae* and pneumococci—by oxygen (or air) early in the course of treatment has some justification and is worthy of careful trial in the more resistant forms of meningitis. The technic is that of a pneumoencephalogram. Oxygen is to be preferred, since it is more rapidly absorbed, giving way to fresh spinal fluid. Late in the course of the disease this procedure would seem to offer very little. Although in our hands this treatment has not caused exus, it is followed by some symptoms of shock and should be reserved for those forms of meningitis relatively resistant to available therapy.

3 *Intrathecal Treatment*—The Infants' and Children's Hospitals of Boston were among the first to discontinue the administration of intrathecal serum, because of its tendency to increase the inflammatory reaction and thereby promote adhesions and the pocketing of pus within the subarachnoid space. The rare exceptions to this rule will be taken up later.

Penicillin, unlike the sulfonamides, is not inhibited by pus and causes very little reaction when injected intrathecally. The blood brain barrier serves to keep it out of the subarachnoid space even when there is a good blood level. On the other hand, it disappears within one or two days (depending on the individual case) from the subarachnoid space, and must be reinjected intrathecally at intervals of twelve to twenty-four hours for maximum effectiveness. Except in mild infections, a spinal fluid level of penicillin should be determined daily during the critical stages of the infection.

The intrathecal injection of heparin (or a comparable anticoagulant) in 1 cc. doses of 10 mg. or more in normal saline every twenty-four to forty-eight hours appears to have theoretical advantages in the di-

rection of delaying the formation of fibrinous adhesions. The exact dosage and interval has not been worked out, nor the possible combination of this method with oral dicoumarin or intravenous heparin. Their maximum effectiveness would appear to be early rather than late in the course of the disease.

4 Observation of the Results of Treatment—Of course the clinical response of the patient is of great value but it may lag several days behind cerebrospinal fluid signs of improvement. These signs are (1) fall of total protein and rise of sugar levels, (2) fall of white cell count and increase in relative number of lymphocytes, (3) disappearance of organisms from the smear, and (4) sterile cultures.

Treatment of Particular Types of Meningitis—With these general outlines of treatment in mind and at the risk of being somewhat dogmatic, one may specify certain measures applicable to particular types of meningitis. Admittedly, therapy is in a state of flux and continuous improvement. What seems up-to-date today may soon need revising the light of later discoveries.

Meningococcal Meningitis—This usually responds well to all the commoner sulfonamides. In fact, after adequate dosage of a sulfonamide, the spinal fluid is usually sterile within six to eight hours. If the response is delayed one should consider the possibility of sulfonamide resistance or a pocketing of pus within the subarachnoid space or inside the ventricles. The latter contingencies are commoner in infants. If the organism is sulfonamide-resistant, intrathecal or even intraventricular, penicillin may be substituted. Intravenous antiserum is very rarely necessary, except possibly in infants.

Five days after the spinal fluid becomes sterile and otherwise shows signs of improvement, sulfonamide therapy may be discontinued provided the general condition of the patient corroborates the laboratory findings. One should be particularly conservative in interpreting signs of improvement in infants who were sick more than three days before therapy was instituted or who responded slowly to treatment.

Influenzal Meningitis—If the meningitis is caused by a respiratory strain of *Hemophilus influenzae* of relatively low virulence, spinal fluid drainage by lumbar puncture, possibly combined with sulfadiazine, is probably sufficient.

If the strain is type B, sulfadiazine and specific antiserum are indicated. Even in "mild" cases it seems wise to give antiserum without delay. While concentrated horse serum (Massachusetts State) intramuscularly in large doses (180 cc) has cured children with meningitis quite promptly, at present intravenous rabbit serum (Squibb)* is the method of choice. It has been standardized in terms of precipitable antibody nitrogen, each vial containing 25 mg.

Mild cases should receive at least 50 mg and severe cases 150 mg.

* Ederle may soon have a similar rabbit antiserum available commercially.

as the initial dose. Alexander suggests that the severity of the infection is best judged by the spinal fluid sugar level. When, by virtue of some degree of immunity or the inhibitory action of sulfadiazine on the organisms, the patient has been ill with meningitis a week or more, less serum may be required to effect a cure or localization of the infection.

Meningitis caused by *H. influenzae* type F has been encountered twice in this clinic, as contrasted with approximately 180 cases caused by type B. One was cured by type F rabbit antiserum.*

Sulfadiazine should be continued at least two weeks after the spinal fluid has become sterile.

In a few instances, improvement follows the administration of the above measures, but spinal fluid cultures continue to show organisms in small numbers. The intrathecal injection of 1 to 5 cc. of rabbit antiserum after spinal fluid has been withdrawn or after the latter has been largely displaced by oxygen, may bring about a walling off and ultimate cure of the infection.

Tuberculous Meningitis—Although several antibiotic agents have been brought forward for use against tuberculous infections in human patients, none are of proved value. Symptomatic treatment of the patient is in order, however, and the most promising of the newer agents, such as streptomycin, may be given a trial.

Pneumococcal Meningitis—The treatment consists of sulfadiazine in doses sufficient to maintain blood levels of 10 to 15 mg. (or more) per 100 cc. until the spinal fluid has been sterile for two weeks. When pocketed pus is suggested, the drug should be given until this risk has subsided. Penicillin is of paramount value and should be given intramuscularly and intrathecally in generous amounts (see general principles, above).

At the present time, the value of specific antipneumococcus serum as an adjunct to these measures is unknown. Experience may well show that some patients, particularly infants, would derive additional benefit from this therapeutic agent.

Streptococcal Meningitis—As mentioned in the general discussion, an attempt should be made to eradicate parameningeal infections. This is particularly true of streptococcal meningitis, which so often traces its origin to a paranasal sinus or mastoid infection.

Penicillin intramuscularly and intrathecally effects cures quite regularly, but the commoner sulfonamides require fewer lumbar punctures and other injections and in general are to be preferred. In resistant infections, penicillin may be given intrathecally along with sulfadiazine by other routes.

In the most severe infections, immunotransfusions of serum or compatible blood are of theoretical value. The organism must first be iso-

* Courtesy of Dr. Leah Seidman.

lated and the donor whose fresh defibrinated blood exhibits optimal phagocytosis is selected

Staphylococcal Meningitis—Penicillin is now the drug of choice in meningitis due to the *Staphylococcus aureus*, although cures have been reported following the use of sulfonamides, particularly sulfathiazole. Large doses should be given early in the course of treatment. Abscesses should be drained.

Meningitis Due to Escherichia Coli—To date, all but three patients suffering from this type of meningitis at the Infants' and Children's Hospitals have died. There are reports in the literature (*Lancet*, 248 176 [Feb 10] 1945) of adults who were successfully treated with 30 gm of urea and 2 gm of sulfadiazine by mouth every four hours.

It is possible that meningitis caused by some of the other gram-negative bacilli would respond to this treatment. Transfusions of blood may be worth while.

Conclusion—In conclusion, one should emphasize that early recognition of meningitis is of extreme importance and time and thought spent in the first few days of treatment usually pay big dividends. One should not be discouraged by seemingly hopeless situations or slow response to treatment. Adequate citizens capable of useful and happy existence may be the reward of perseverance.

THE TREATMENT OF COMMON ARTHRITIC CONDITIONS

FRANCIS COOLEY HALL, M.D., F.A.C.P.*

TREATMENT of common arthritic conditions is the treatment of a variety of diseases presenting symptoms and signs in and about joints. To many, symptoms of arthralgia or arthritis seem mysterious, both as to cause and treatment, and the only way to help the patient seems to be to prescribe one of the analgesics such as salicylates. This is often done with the realization that a certain number of people have joint pains which will disappear anyway if serious damage to the articular tissues has not occurred, while the aspirin temporarily relieves the pain, but it is also given with the feeling that no one knows anything about arthritis, and nothing much can be done about it. Granting our limited knowledge, we think that most patients can be relieved and the joint disease arrested in a high percentage of cases, and this article attempts to set forth a means of approach to the problem.

Certain general statements need to be repeated again and again in order to keep a proper perspective and to avoid getting into a rut which leads to the treatment of all joint disturbances in the same way, using the latest popular therapy. (1) Joint pain may be due to one of many different conditions, and it is important to find out in each individual case what particular factors produce the joint pain. (2) A person who seeks a doctor because of joint pain is sick. It is important to start with this premise in mind and to search most diligently for the underlying causes of this ill health or subnormal state. One would then consider the joint pain as the smoke of the fire. This should result in a most careful study of the patient as a whole. (3) It follows that the whole patient should be treated in addition to the joint condition.

The patient should be studied with three objectives in mind: (1) to determine whether he has a nonarthritic condition which is part of some recognizable disease not arthritis, (2) to determine whether we are dealing with a twilight zone of arthritis—a mild form of joint pain and swelling which we speak of as arthralgia—and (3) to determine whether we are dealing with a true arthritis. Careful study should easily rule out some of the diseases frequently, carelessly diagnosed as

from the Second and Fourth Medical Service (Harvard) Boston City Hospital and the Department of Medicine, Harvard Medical School, and from the Robert Breck Brigham Hospital, Boston.

Junior Visiting Physician, Boston City Hospital. Instructor in Medicine, Harvard Medical School, Senior Visiting Physician, Robert Breck Brigham Hospital.

arthritis, but it is important to keep in mind others such as Paget's disease, neuritis from avitaminosis, osteomalacia, pernicious anemia with spinal cord changes, hyperparathyroidism, Parkinson's disease associated with muscle rigidity rather than tremor, carcinoma, spinal cord tumor, ruptured intervertebral disk, various conditions causing edema such as nephritis, hypoproteinemia, myxedema, scleroderma, sclerodactylia and dermatomyositis

CLASSIFICATION

The twilight group of diseases associated with joint pains which are called "arthralgia" because we do not yet know that they represent true arthritis, might include postural joint strain, thyroid deficiency, menopausal state or ovarian deficiency, vitamin B complex deficiency, psychologic states and emotional conflicts, and physical fatigue

A convenient classification* of cases of true arthritis follows

I ARTHRITIS OF KNOWN ETIOLOGY

A Traumatic arthritis

B Infectious arthritis

- 1 Associated with diseases due to known specific organisms such as the gonococcus, staphylococcus, streptococcus, pneumococcus, meningococcus, tubercle bacillus, typhoid bacillus, *Treponema pallidum*, the brucella group, *Bacillus dysenteriae*, the organism of lymphopathia venereum, etc
- 2 Associated with diseases probably infectious, such as acute disseminated lupus erythematosus, erythema nodosum, ulcerative colitis and periarteritis nodosum

C Metabolic arthritis, gout, scurvy, ochronosis

D Allergic arthritis, serum sickness

E Neuropathic arthritis, rabes dorsalis (Charcot's joint), syringomyelia, leprosy, yaws, hemiplegia, peripheral nerve lesions

II ARTHRITIS OF UNKNOWN ETIOLOGY

A Rheumatoid arthritis (atrophic, proliferative, or chronic infectious arthritis) This also includes Still's disease, rheumatoid spondylitis (Marie-Strümpell, von Bechterew's types) and psoriatic arthritis

B Degenerative joint disease (degenerative arthritis, hypertrophic arthritis, osteoarthritis, and German arthritis deformans)

C Rheumatic fever

III MISCELLANEOUS TYPES OF ARTHRITIS

Fibrositis, hemophilia, purpura, pulmonary osteoarthropathy, intermittent hydroarthrosis, hysteria

It is frequently stated that one should make the diagnosis of arthritis early, before there is clear-cut clinical or roentgenologic evidence of damage to the essential joint structures. This is a difficult thing to do, and even physicians who are spending most of their time seeing arthritic patients find it so. They would even disagree as to the nature of the disease in many early cases. It is for this reason that in early cases it is important to take the matter seriously and in taking the his-

* Cabor, R. C. and Adams, F. D. *Physical Diagnosis*. Baltimore, Williams & Wilkins Co., 1942

tory to look for some of the pathologic states and common errors of living which are found in patients with arthralgia or with true arthritis. Correcting such abnormalities will often lead to improvement of the patient's general health and to a relief of the joint pains. The abnormalities most commonly found are discussed below.

ARTHRALGIA

1 Joint Disturbances Due to Fatigue—It is quite common to find as a background of joint disturbances habits of living that lead to real fatigue. Sometimes the patient is getting to bed late at night because he is unable to sleep. In such cases the cause of the sleeplessness needs to be found. Usually one finds that a person is working hard all day under pressure, sits up late at night to read or do other things, and averages six or seven hours of sleep when eight or nine hours are needed. Sometimes it is ambition that drives a person to overwork and too little sleep, sometimes it is financial necessity accompanied by worry. The result is a sapping of his physical vitality. Where such lack of sleep is found, we often prescribe twelve to sixteen hours daily in bed, and we usually prescribe this even when there is no deficiency in sleep. Helping the patient to learn what to leave out in life should be a constructive part of therapy where overwork and too little sleep are factors.

2 Joint Pains Resulting from Emotional States—It follows from the above that the drive of strong emotional states leading to overactivity and too little sleep can be important, but at other times one finds home conflicts which may be enormous and which may even require psychotherapy. At the moment one finds worry about sons in the war interfering with sleeping and eating.

3 Postural Joint Strains¹—These can be important as factors in causing pain in the cervical spine, or in the lumbar and sacroiliac regions, or in the knees or feet of patients who obviously stand incorrectly. Strain alone may be present, or it may be superimposed on arthritic conditions of other origin. Where postural strains exist, they should be relieved by corrective exercises for back or feet plus in many cases back braces, foot plates, and short periods of rest throughout the day in hyperextension. Often there is some reason for the poor posture other than bad habits and ignorance—conditions which cause easy fatigability, such as too little sleep, thyroid deficiency, or some other disease.

4 Joint Pains of Thyroid Deficiency²—If marked, thyroid deficiency should be easily recognized but we occasionally see a patient who does not have all the characteristic symptoms and signs, but does have a low metabolism and a high blood cholesterol, and whose joint pains respond to thyroid gland therapy.

5 Joint Disturbances Associated with Nutritional Deficiency—The two most common findings in patients complaining of joint pains are in-

complete nutrition and the glandular imbalance of the menopause.³ As we have watched patients with these conditions, we have come to the conclusion that these deficiency states lead to increased vulnerability of tissues so that the trauma of ordinary use—trauma to joint tissues and to muscles and tendons—produces pain and various degrees of disability. We became convinced of this with regard to the menopausal group by an unusual experience with one patient.

The patient, who was at the physiologic menopause, had many menopausal symptoms and was hospitalized because of the extreme pain in most of her joints. This was accompanied by hypertrophic arthritis in the fingers. However, it became quite clear that the tissues all over the body were abnormally sensitive. Pressure over the forearm would make her cringe. Taking the blood pressure caused pain. Abdominal examination was unsatisfactory and caused discomfort, and pelvic examination was impossible for the same reason. Three weeks later, following therapy with large doses of estrin, most of this sensitivity had disappeared, and all examinations could be made without distress.

We have seen instances somewhat less striking than this in many patients at the menopause. We have seen nothing as dramatic in cases of incomplete nutrition, but certain responses have suggested that incomplete nutrition may well be responsible for somewhat similar symptoms.

Many physicians apparently are unaware of the prevalence of incomplete nutrition in patients with joint disturbances. It is pointed out that most people eat a satisfactory diet. However, if one watches tongues, skin and eyes for evidence of incomplete nutrition, one finds a great many more cases of avitaminosis in patients with seemingly adequate diet than one would believe possible. We find only a few instances of an *incomplete intake* of the various protective foods. Among women the most common foods left out are milk, eggs and meat (or protein foods). This last is more common of late, and we have observed quite a number of persons with the total protein of the blood low and some edema of the ankles, which with the history of incomplete intake of protein would definitely indicate hypoproteinemia. A certain number of people have an *increased requirement* for protective foods. The requirement is definitely increased by long hours of work and short hours of sleep. It is increased by alcohol, sugar, hyperthyroidism, pregnancy, and infections.

The most common cause of incomplete nutrition, however, seems to be hyperperistalsis resulting in *incomplete absorption* of food. The most dramatic cases are seen in patients with diverticulosis or an irritable colon. They come with a history of having had three to five bowel movements a day over a long period of time, or intermittent attacks of this hyperperistalsis. Such patients usually show very definite evidence of B avitaminosis in the tongue and skin, but in all probability there is a deficiency of all known vitamins, plus a probable deficiency of other food factors that we do not yet know. Less striking, but

apparently very important, are instances of incomplete nutrition in patients who are convinced that they require a daily cathartic and who never have normal, formed bowel movements. In all such patients it is obvious that the food is not being processed and absorbed within a normal period of ninety or 120 hours, but is being hurried through the bowel as Burnett⁴ has shown. Patients with these conditions can have the most bizarre symptoms and signs even when obese—symptoms such as are mentioned in the literature on avitaminosis.

One of our earliest cases was quite dramatic in its symptoms and response to therapy. The patient was an extraordinary 70 year old woman who until a short time previously had been running a newspaper in a small town, and had more or less "sparked most of the town activities. She was a widow with no special ties and she decided to come to Boston to paint portraits as an avocation. Her history indicated that she had always been overactive and careless about her eating. She had had intermittent gastrointestinal disturbances with diarrhea, and she had left out of her diet many important foods. Once in Boston she soon found herself too tired to do her marketing or painting. The arthritis of which she complained was not explained. One found very little except mild hypertrophic changes in certain joints and the symptoms were all out of proportion to the physical findings. There was some tenderness about the joints and a tremor of the right hand which we could not explain. Her tongue and skin showed mild signs of vitamin B deficiency. We prescribed sixteen hours in bed in twenty-four as complete a diet as possible, somewhat low in roughage but containing a large amount of protective foods such as milk, eggs and meat, of which she had been eating but little. We gave her large amounts of vitamin B, covering the other vitamins by diet, and several times a week gave her an injection of "vitamin B complex parenteral." In one month most of her symptoms had entirely disappeared and in the last five years she has remained well by following a proper diet and taking supplementary vitamins.

One wonders whether such a state can lead to true arthritis, we have cases which seem to indicate that it can do so.

An example is a doctor's wife, now over seventy who had been having arthritis in the knees and hips for some years before she was seen five years ago. She was found to have diverticulosis, but because of her love of salads, cole slaw and other green vegetables and fruits she persisted in eating such foods, and for years she had had considerable gastrointestinal difficulty with frequent periods of diarrhea always with a great deal of flatulence and always or three soft bowel movements a day. When seen, she had a tongue typical of B avitaminosis with ulcerations thought to be due to lack of nicotinic acid or riboflavin. Her skin was somewhat dry. At the worst she had to live a very restricted life because of the joint pains which at one time involved the fingers, wrists and other joints in a transitory fashion causing marked hypertrophic changes in the hips and knees and marked limitation of motion. She was unable to take vitamins by mouth without increasing the gastrointestinal symptoms. For several years, therefore, she has had two or three injections a week of liver or vitamin B complex. The result is that her arthritis, which appeared to be of the mixed type, has been less and less conspicuous, and her activities are consistent with those of a woman of seventy-three.

It seems to be important in such cases to reeducate the patients with regard to diet and bowel habits. One has to point out the necessity of

thinking of the gastrointestinal tract as a factory for the processing and absorption of food, and one must encourage the patient to have only one formed movement every day or every other day. Often it is quite a psychological hurdle to convince such patients that dire things will not happen if the bowels are kept really slow acting. One has to plan the diet so that there will be a proper amount of green vegetables and fruit in a form that can be tolerated. Such patients often have to give up indefinitely raw vegetables such as salads and celery, and rough foods like corn and sometimes spinach. Bismuth or kaolin and paregoric, to be taken before going to bed each night, may be of value at times, when only mild soothing of the bowel is needed. Sedatives sometimes help such hyperperistalsis. The presence of hyperthyroidism needs to be ruled out, and emotional conflicts resolved, if present. Supplementary vitamins of all types would seem to be indicated in very large doses. Until one is convinced that absorption is complete, especially in older persons, parenteral therapy is often indicated. In such cases we give very large doses of vitamins by mouth, using the multiple vitamin preparations and 2 cc of B complex with a liver base intramuscularly twice a week. As these persons are sick, it is important to treat them as such, with extra quotas of rest which of course cut down the nutritional requirements.

6 **Menopausal Arthralgia**⁸—This type of joint pain should be easily recognized if sought. The diagnosis is clear when the arthritis occurs within weeks or a few years after destruction or removal of the ovaries, and when definite symptoms of the menopause are present. It is usually possible to detect this type of arthralgia when it occurs at the physiologic menopause. It may be easily overlooked when other contributing factors to the patient's poor health are present, such as those previously mentioned. It is apt to be out of mind entirely when it occurs superimposed on a definite type of arthritis such as the hypertrophic type or the rheumatoid type. Its importance sometimes in such conditions cannot be overstated.

An example of this occurred in a nurse of 56 who came to the hospital severely crippled with rheumatoid arthritis of ten years' duration. In addition to the permanent joint changes there was marked pain in the left hip requiring her to be put into a plaster shell. Improvement seemed to stop after a few weeks, and the whole history was again searched for leads suggesting some specific etiology. Though she had denied any menopausal symptoms, we had suspected that her sleeplessness, her depression and nervous tension, and her dissatisfaction with the temperature of the room at night, however we kept it, represented menopausal symptoms. Further questioning brought out other symptoms, especially mental depression. The use of estrin produced an almost complete personality change in the patient and started her toward improvement. Instead of being bedfast in the last few years she has become increasingly active, and though we do not attribute this to the sex hormone alone, we feel that it contributed to her improvement in no small measure because improvement in the joints as well as in her general health occurred within a few weeks after she took this material.

We still do not know whether this glandular readjustment of the menopause, or estrin deficiency, can in itself cause joint changes that we term arthritis. As one watches patients with arthralgia alone, those with arthralgia plus tissue changes in a few joints, and finally those with arthralgia plus a good deal of arthritis, one cannot but note what appears to be a transition from mild to severe cases. Intensity and duration of the condition seem to influence the joint tissues in producing the clinical picture found. One wonders then whether estrin deficiency or the glandular imbalance of the menopause may not play a major role in some cases developing into true arthritis. One could set up an hypothesis that (1) the tissues are made more vulnerable by ovarian deficiency to the trauma of ordinary use and the continued trauma results in chronic inflammation and the changes we think of as hypertrophic arthritis. Other possible effects of sex hormone or lack of it are suggested by the work of Weisberger,⁵ who demonstrated that (2) in certain women who have B avitaminosis large doses of vitamin B will not change the tongue and skin toward normal until estrin has been added. There is, furthermore, increasing evidence that (3) castration in laboratory animals may increase susceptibility to infection, while fortification by estrin may increase resistance, as shown by Aycock⁶ and others. We believe we have observed these principles exemplified in patients with arthritis. Lest the diagnosis of infectious arthritis or of rheumatoid arthritis be too easily made in patients at the menopause because of the presence of an elevated blood sedimentation rate, it is important to state that elevated rates are the rule in castrates with menopausal symptoms, but without joint pains.⁷

For estrin therapy we favor giving the amount that will eventually produce swelling or tenderness of the breasts, pelvic symptoms such as those manifested at menstruation, or mild leukorrhea. The patient's cooperation in reporting these symptoms must of course be obtained. These large doses are necessary to make certain that enough estrin is given. Once a saturation of tissues occurs, smaller maintenance doses are required, and these should be just enough to prevent breast and pelvic symptoms. Treatment should be stopped for a week or ten days every six weeks. We use doses of 10 000 rat units three times a week to 2000 rat units one to three times a week, depending on the severity of the symptoms. The intramuscular route is preferred until the symptoms are under control, when one substitutes oral medication using 0.5 mg. of progynon D-H tablets two to three times a day, or 0.5 to 1.0 mg. of enteric-coated stilbestrol tablets once a day at bedtime. Again, we favor stopping this course of therapy every six weeks for a period of at least one week. Starting with an oral preparation which may be very insufficient, or which like stilbestrol may upset the gastrointestinal tract, has not been successful with us, for one of the things that the patient needs in the first six or eight weeks of treatment is the evidence that she is better, and if medication is given that upsets her

or if improvement is so slow as to be unconvincing, she is likely to lose confidence in the whole program

Not infrequently there is evidence of incomplete nutrition as well as a menopausal problem in a patient, and one cannot help but speculate as to whether patients with severe menopausal symptoms and those with symptoms that continue for many years may not lack certain chemical building stones necessary for the glandular readjustment. It would seem basically important in such patients to make sure that any nutritional deficiency is corrected. Surely the menopause should be a relatively normal stage of life and not attended by as much difficulty as we often see. It is our impression that the patients who receive supplementary vitamins as indicated make the best response and require estrin treatment for a shorter length of time than when vitamins are not used, and we suspect that some of these patients might do well with simply the nutritional approach alone.

THE ARTHRITIDES

Much of what we have noted in respect to arthralgia applies equally to arthritis, for the various conditions we have mentioned are commonly found in persons with chronic arthritis, but one of the first important things to do in studying a patient is to determine if possible the type of arthritis with which one is dealing, to the end that where the cause is known, the treatment may be precise. Traumatic arthritis is usually clear-cut and the chronic microtrauma of poor posture is usually easily recognizable. Sometimes only trauma is present. It is a contributing factor in practically all other types of arthritis. The possibility of the arthritis being due to infection will naturally be kept in mind and, so far as possible, infection will be treated specifically by modern drugs or removed surgically. Space does not permit the inclusion in this article of a discussion of gout or allergic arthritis or the neuropathic group.

It is especially in the two main types of chronic arthritis, namely rheumatoid and hypertrophic arthritis (or degenerative joint disease), that what we have noted in the preceding paragraphs seems to apply. We still do not know the cause of these two types of arthritis. The rheumatoid type is still generally thought to be due to infection, while degenerative joint disease, or hypertrophic arthritis, is thought to be due to the wearing out of the joints. Descriptions of the clinical pattern and the pathological findings in these two types can be found in textbooks. The fact that there are so many mixed types raises again the old question as to whether both types may not have common factors in their etiology, with the character and intensity of the irritant, its duration, plus the presence and absence of the trauma of use resulting in the pathological findings which we use to distinguish the two types of joint disease. Joint tissues can respond to various irritants or traumas in only a limited number of ways, and one could offer con-

siderable support for this theory. Granting that the rheumatoid type seems to be most closely allied to known infectious processes in joints, and that it responds in a considerable number of cases to gold salts therapy which is thought to act directly or indirectly on an infectious process, still one cannot help wondering why one patient throws off infection easily while another seems to have no resistance to such infection. One must conclude that the treatment of the whole patient and the elimination of all contributing factors are important in both types, even if infection should be proved to be the cause of rheumatoid arthritis.

Rheumatoid Arthritis—Serious treatment of the patient as a whole is especially important in rheumatoid arthritis. Occasionally one sees a case in which infection seems clearly to be responsible for the arthritis, but usually there is no such history. Much more commonly one finds a history of depletion with overwork, too little sleep, poor eating habits, worry, loss of weight, continued mechanical irritation of already damaged joints with the help of "pain-killers," and a cathartic habit until disability is fairly complete. Treatment in such cases, if results are to be permanent, requires a maximum of rest so that the patient obtains at least sixteen hours a day in bed, even in early cases, and in addition the best possible diet and one calculated to keep the bowels slow-acting. Supplementary vitamins are given in large doses, especially if there is evidence by skin and tongue of incomplete nutrition—a common finding. Enough aspirin is prescribed to provide rest. It is important to keep the muscles, the circulation, and the nervous system in good condition by exercises for the trunk, with a little motion for the involved joints. Use of the weight-bearing joints may have to be discontinued for a while, however, for sore knees or hips will not improve, if badly irritated, as long as weight bearing continues. Heat to the involved joints two or three times a day gives considerable comfort in the early or mild cases, especially where there has been an obviously marked fatigue or deficiency.

The measures outlined will in most cases lead to improved health, which is soon followed by improvement in the joints. Unfortunately, some patients will not improve under such a program alone, and in these cases one must consider the risk of gold salts therapy. If the liver and kidney functions are normal, and there is no marked avitaminosis, the risk of giving gold salts is probably less than the risk of withholding it. However, we have become very conservative in its use as we still have numerous patients in whom gold salts therapy has had to be stopped because of skin itching, irritation of the kidneys, or the development of anemia or a low blood platelet count. We have seen patients who were greatly benefited by one course of therapy but whose arthritis recurred. In most of these the further use of gold salts was contraindicated, in others it proved to be of little value. Inasmuch as the infectious origin of some rheumatoid cases is in doubt and since

many cases given this diagnosis present contradictory pictures one wonders whether other types of arthritis might not be included in this classification. In the circumstances it seems important in an individual case to have an open mind and feel one's way along, doing everything possible to build up the general health of the patient, and not relying on any one drug.

We have used gold therapy in perhaps 150 cases of rheumatoid arthritis. We are not enthusiastic about its value when it is used alone, and we still are afraid of gold, but we could point to numerous cases that did not respond to treatment until gold was used, and that appeared to be completely arrested following its employment. In using gold salts we generally give 10 mg. of a product such as solganol-B in oil from two to four doses at intervals of four to five days, then two to four doses of 25 mg. at weekly intervals, then maximum doses of 50 mg. once a week. We have continued this program until the patient's symptoms were markedly lessened, or until a total of 1 gm. of the salt has been given. If the patient's symptoms are greatly improved at any point in the treatment we increase the interval between doses to two, three or four weeks. Even when the arthritis seems to be under good control, we continue to give 50 to 100 mg. once a month for six months more.

We are conscious that the doses advised are smaller than those ordinarily used. Our results are probably less spectacular, therefore, than those of many others who report on the use of gold salts. It should be stated, however, that even with these smaller doses we have seen enough patients with prolonged and disfiguring dermatitis, with prolonged periods of albuminuria, or with falls of blood platelets below 200,000 per cc. to make us eager to avoid the more frequent toxic reactions that all agree can result from the larger doses. We prefer, first, to use every other means possible to help our rheumatoid arthritic patients, then if these means fail to use as little gold as possible, and finally if gold is used to stop it as soon as possible.

During the process of treatment it is particularly important to educate the patient in the art of living, and then to keep in touch with him after he is considered to be well. Crippled joints can be reconstructed to an extraordinary extent by the orthopedic surgeons, and where it is perfectly clear that the arthritic process is quiescent as noted by the absence of any new joint disturbance, the absence of morning stiffness, and the absence of an elevated sedimentation index, one can expect operative procedures on joints to be remedial without the development of stiff joints from the operation.

Degenerative Joint Disease and Hypertrophic Arthritis (Osteoarthritis)
—Trauma is considered to be the major factor in the development of hypertrophic arthritis. Trauma is unquestionably an important factor in all joint diseases and needs to be so considered, yet careful studies of patients seem to indicate that an x factor must be added to the

trauma. A large number of women develop hypertrophic changes in the fingers at the menopause, which suggests that the menopause can be one of those x factors. Incomplete nutrition may be another such factor. Certainly most students of hypertrophic arthritis do not believe that infection plays a role. If there is an x factor present, they believe it must be of metabolic origin. In some cases thyroid deficiency seems to be responsible.

The presence of hypertrophic arthritis is apt to be minimized by physicians, and patients are told that the disease will never cripple them and that not much can be done about it, anyway. We do not agree that nothing can be done. In menopausal cases we have seen hypertrophic nodes on the fingers become actually smaller, as measured by jewelers' rings, when the patient was given adequate estrin therapy. We have seen patients with marked hypertrophic changes in the spine or knees lose the pains, which were presumably due to these hypertrophic changes, when trauma was removed and proper nutrition given. It does not seem to us that the hypertrophic lesions seen by x ray plays any convincing part in the causation of pain unless the changes are excessive. One sees marked arthritic changes in the spine, for instance with a history of no pain, and on the other hand, considerable pain may be present but little change is seen by x -ray. The cause of the pain may be one of the factors already mentioned, such as estrin deficiency, nutritional deficiency, or even infection plus trauma. In addition there may be a history of marked fatigue, postural joint strain, obesity from overeating of the wrong foods with under-eating of the protective foods.

When the knees or hips are involved, the disease cannot be treated lightly. Normal use of already damaged weight-bearing joints will aggravate the damage as the years pass. A once damaged joint will degenerate more rapidly than one not damaged. In addition to the general measures the cardinal principle of treatment is to keep the patient off his feet when there is pain in the hip or knee. Though cartilage is known to have little power of repair, the inflammatory changes in the other joint structures may often be arrested as indicated in the following example.

A patient, now 70 years old was seen fifteen years ago for the first time. She came to the office in a wheel chair pushed by her husband and she moved on crutches. She had had involvement of the right hip for at least five years. She had been overweight and had eaten an adequate diet. The condition appeared to have started at the menopause, but she was well past that event. She had less than 50 per cent of normal motion in the right hip. The motion was painful and the x ray showed a flattened head of the femur with obliteration of the joint space. She was a very cooperative patient and wished to do everything possible to get well. Ordinarily in five years such a patient walks with a great limp still has a great deal of pain, and the disability has markedly increased. For some years now she has used neither crutches nor cane, and rarely has pain in the hip. While she was given various types of medication, we believe that

her improvement was due to the fact that she was willing over a long period of time to go to bed whenever she had pain, and to stay there until the pain passed. At first she was in bed a great many weeks. As the years passed, she would occasionally have to go to bed for only a few days at a time. She had learned that her damaged hip, if used beyond a certain point, would always give pain, but she had become very alert to recognizing stiffness after sitting as the first evidence of increased joint irritation. She would then spend a few days in bed, and would be able to be active with restrictions for some weeks before having to do the same thing again.

Patients without the marked disability present in this patient will often recover almost normal walking capacity under such a program, because the reserves of the joint seem to be as great as the reserves in other organs and a patient can be fairly active in spite of a good deal of joint damage. This attitude is similar to that taken in heart disease, in which the patient has to build up his cardiac reserve and then learn to live within it. We have other patients who had had similar records. Some have taken thyroid or estrin, others have needed to watch their diet or their bowels carefully and take supplementary vitamins, but they all have kept off their feet when there was pain or stiffness. Patients with hypertrophic arthritis often tend to be overweight while those with rheumatoid arthritis tend to be underweight. It seems important to put weight onto the latter and to take weight off of the former. However, we are convinced that the removal of weight by dieting must be done slowly, carefully, and with great stress on protective foods and supplementary vitamins. The removal of weight seems to help definitely the nutrition in joints and it also serves to remove in part the trauma that overweight puts onto already damaged weight-bearing joints. Thus again stress needs to be laid on treating the patient's general condition as well as his joints.

Although many cases of arthritis will respond to the therapeutic program which has been outlined, not all will do so. We cannot reverse the process and expect to regain a normal joint in any case in which definite damage has been done. In such instances the patient has to learn to live within his limitations, although those limitations may be lessened by the orthopedic surgeon. We do believe that this multi-angled and varied approach to the treatment of joint diseases gives us fewer failures than we have had in the past.

SURGICAL INDICATIONS AND TREATMENT OF PRIMARY CANCER OF LUNG, BRONCHIECTASIS AND LUNG ABSCESS

JOHN W STRIEDER, M D *

PRIMARY CARCINOMA OF THE LUNG

THE increasing frequency with which cancer of the lung has been reported as a cause of death in recent years has aroused considerable speculation whether the increase represents a real change in the incidence of this form of malignant neoplasm or is merely the result of improved methods of diagnosis in combination with a more careful search for a disease that has attracted attention because it is reported more frequently than it has been in the past. Dorn states that between 1914 and 1930 the death rate from cancer of the lungs and pleura increased by nearly 400 per cent, as compared with an increase of 20 per cent for all forms of cancer combined. Slightly more than 8000 new cases of primary cancer of the lung are diagnosed and receive treatment for the first time each year. Recently it has been shown that the lung ranks second only to the stomach as the primary site of cancer.

Any male patient of middle age or beyond, who develops cough and expectoration, with or without hemoptysis or blood-streaking, and who cannot be shown to have tubercle bacilli in the sputum, should be considered to have bronchogenic carcinoma until it is proved unequivocally that there is some other reason for his symptoms.

Diagnostic Procedures—Roentgenography—The first step leading to diagnosis is a roentgenogram of the chest. In most cases, this simple procedure suggests the diagnosis either by indirect evidence, such as atelectasis of a lobe or lobes due to an obstructive bronchial lesion, or by the more positive evidence of an infiltrative hilar lesion or parenchymal tumor. Alexander states that despite the prevailing impression, most circumscribed intrathoracic neoplasms are intrapulmonary and malignant. All pulmonary abscesses and suppurative lesions should be considered as resulting from bronchogenic carcinoma. In general, one may say that the roentgenogram shows the tumor, which may be relatively tiny, less frequently than its result, which usually predominates in the clinical picture. In rare instances, the roentgenogram is negative.

Bronchoscopy—The second step by which a positive diagnosis can best be made before operation is almost always bronchoscopy. Various

* Assistant Professor of Thoracic Surgery, Boston University School of Medicine, Boston, Massachusetts, Visiting Surgeon in Charge of Thoracic Surgery, Massachusetts Memorial and Boston City Hospitals

authors have stated that a positive diagnosis by bronchoscopic biopsy can be made in from 60 to 75 per cent of cases. If one takes into account the indirect bronchoscopic evidence of fixation, broadening of the carina or bronchial deformity, a presumptive diagnosis may be made in as high as 85 per cent of cases.

Aspiration Biopsy—The introduction of a needle directly into the tumor under fluoroscopic guidance, for the purpose of obtaining a plug of tissue for biopsy, has been advocated by some clinics. In my opinion, this procedure is useful in a limited number of peripheral tumors. It is not, however, entirely without hazard since deaths from air embolus have been reported. It has also been objected to on the theoretical grounds of secondary seeding of the needle track with cancer cells. There is, also, always the possibility of pleural contamination should the area needled be infected.

Examination of Pleural Fluid for Tumor Cells (Mandelbaum Test)—Whenever there is a pleural effusion, it should be completely aspirated and the entire amount centrifuged. The resulting sediment is fixed and examined for tumor cells. If tumor cells are found, the case is inoperable. If the fluid is bloody, it usually means invasion of the visceral and parietal pleura by the growth and also denotes inoperability.

Exploratory Thoracotomy—The problem of what advice to give in the 25 per cent of cases without a positive diagnosis is an important one. In Graham's opinion, the answer is generally fairly simple. If there is a reasonable suspicion of carcinoma, an exploratory thoracotomy should be performed without delay, for in this way many lives can be saved. Too often the advice of the physician has been to wait to see if anything happens. Nothing is gained by this delay, and the usual result is another victim.

Treatment—It is now generally recognized that the ideal in the treatment of primary cancer of the lung is its surgical extirpation by total pneumonectomy. In rare cases, lobectomy may be used, but, as in cancer surgery in general, only by the sacrifice of the entire organ can one hope to achieve the greatest number of cures.

To my knowledge, there has never been an authenticated case of bronchogenic cancer that has been reported as a five-year cure as the result of radiation therapy. It has a limited sphere of usefulness as a palliative measure and may be used in certain inoperable cases.

An analysis of the risks involved in total pneumonectomy reveals an encouraging trend for an operation that must be considered to be technically still in its developmental stage. It is of interest that the mortality figures in three widely separated clinics are strikingly similar. Graham reports three deaths in his last twenty-five cases, a mortality of 12 per cent, and Rienhoff states that in a series of twenty-three cases he had three deaths, a mortality of 13 per cent. In our last twenty-three cases at the Massachusetts Memorial and Boston City Hospitals

we have had two deaths, a mortality of 9 per cent. Such figures are reasonable ones, and should bring home the fact to the medical profession that the operation of total pneumonectomy for primary cancer does not carry with it an enormous operative risk. It has been generally believed. It should be remembered that with this operation the risk is 100 per cent.

The question of the age of the patient frequently enters into consideration of operability. At the present time, there would appear to be no empirical age limit. The general condition, and particularly the condition of the cardiovascular apparatus is more important than the chronological age.

Inoperability—From an analysis of current statistics and my experience, only 10 to 25 per cent of cases of bronchogenic carcinoma are operable when first considered for surgery, a sad reflection on the ability of physicians to recognize this relatively frequent disease in its early and favorable states.

The reasons for inoperability, which, as a corollary, mean late diagnosis and advanced disease, are based on certain findings. These findings have been summarized by Graham as follows:

1 *The presence of bloody fluid* This usually means invasion of the visceral and parietal pleura by the growth. In most cases, the presence of clear effusions also means inoperability; and the finding of malignant cells in such effusions makes it certain.

2 *Paralysis of the corresponding half of the diaphragm, as determined by fluoroscopic examination* This usually is due to invasion of the phrenic nerve.

3 *Paralysis of the left vocal cord in cases of left-sided bronchogenic carcinoma* This usually denotes invasion of the left recurrent laryngeal nerve as it passes under the arch of the aorta.

4 *Severe pain in the thoracic wall or down the arm* This is usually a sign and generally is evidence of involvement of intercostal nerves or of the brachial plexus. The presence of a moderate amount of pain, however, should not preclude an exploratory operation.

5 *Bronchogenic evidence of extension of the tumor into the trachea* This usually contraindicates pneumonectomy, although occasionally it is possible to remove even a part of the wall of the trachea.

6 *The presence of distant metastases* In exceptional cases, it may be justifiable to remove both the lung and a solitary metastasis.

BRONCHIECTASIS

In a recent paper, Riggins concludes, "The morbidity and mortality of untreated and medically treated bronchiectasis is such that the physician who routinely advises young adults with operable bronchiectasis against surgery is assuming a grave responsibility and his probability renders his patient a great disservice."

That bronchiectasis is a surgical disease and that most patients

whom it is discovered should be considered for lobectomy or pneumonectomy is corroborated in a study presented by Perry and King. Basing their conclusions on a follow-up of 400 patients, these authors show that in a twelve-year study the mortality in the nonsurgically treated cases was 26 per cent, 41 per cent of these patients dying within five years of onset and 15 per cent living twenty years or longer after onset. Of the patients who died, 78 per cent died directly from their disease. Some statistical evidence supports the view that patients who develop bronchiectasis before the age of ten do not live beyond the age of forty. Thus, of persons with the onset in the first decade only 9 per cent were living at the age of forty or over. Of the fifty-nine patients who reached the age of forty or over, in only 15 per cent was the onset in the first decade. The operative mortality in 122 modern type lobectomies performed on 116 patients was 3 per cent. The working and living capacity of the traced living patients was considered to be excellent in 67 per cent of the surgical group and in 38 per cent of the nonsurgical group.

The nonsurgical treatment of bronchiectasis is only palliative and because of the low operative mortality rate, simple lobectomy should be advised without hesitation. Even with bilateral disease the risk in bilateral lobectomy—of course in two stages—is frequently not too great. Children stand thoracic operations exceptionally well, and lobectomy early in life is almost certain to obviate the hazards of bronchiectasis that such children must face if they grow to adolescence or adult life with nonsurgical treatment.

Diagnostic Procedures.—1 *Bronchoscopy*—All patients suspected of having bronchiectasis should have bronchoscopy performed during the course of the work-up. Bronchiectasis is notoriously secondary to tumors, strictures and foreign bodies and frequently the true situation is revealed only during the course of the bronchoscopic examination. Moreover, the localization of the disease by the bronchoscopic visualization of the lobar or segmental bronchi from which purulent secretions are draining is of great value in determining operability and planning the surgical program.

2 *Bronchography*—The only certain procedure by which a diagnosis of bronchiectasis may be made, and its extent determined, is by the introduction of iodized oil into the tracheobronchial tree and the making of bronchograms. Before any surgical program can be planned, indeed before it can be determined if surgery is indicated, good bronchograms must be made. There are several technics by which iodized oil is introduced in bronchography. These include the intratracheal, transtracheal and supraglottic methods, all of which are in common use in various clinics today and good bronchograms may be obtained by the operator experienced with any of them. Because of its simplicity the intratracheal catheter is used in my clinics, but the primary desideratum is the adequate filling of all five lobes of the lungs. Many

of the early disappointing results in the surgery of bronchiectasis are directly attributable to undertaking surgery on the basis of poor or inadequate bronchograms

The procedure is painless, although, at times, arduous for both the patient and the operator, but it must be persevered in to achieve the desired result. It does not require hospitalization. Not infrequently two or more sittings are necessary before complete and satisfactory bronchograms are obtained.

Treatment—Surgical—Operation should not be undertaken on febrile patients who are in the acute or subacute phases of a pneumonitis which frequently complicates bronchiectasis and often is the incident which first leads to the diagnosis. Nor should afebrile patients, who have copious foul sputum, be considered for immediate operation. Bitter experience in the early days of this type of surgery has demonstrated that disaster follows such misguided efforts because of the complications of infection of pleura, mediastinum or chest wall due to the presence of virulent anaerobic organisms in this phase of the disease. These patients should be prepared for surgery, as will be discussed below under nonsurgical treatment.

Assuming the patient to be under 35 to 45 years of age, and otherwise presenting no serious contraindications in so far as his general condition is concerned, the indications for and types of operation may be considered under the following headings:

1 *Unilobar disease* Bronchiectasis localized to one lobe or a segment of a lobe is the ideal indication for surgery. In this situation, lobectomy or partial lobectomy (segmental pneumonectomy) may be recommended with the expectation that the operative mortality will be less than 3 per cent, and the chances for complete cure close to 100 per cent. As has been suggested by the foregoing, disease localized to a definite anatomical segment of a lobe, as the lingula of the left upper or the dorsal or basal divisions of the lower lobes, may be treated by partial lobectomy, thus conserving normal pulmonary tissue.

2 *Multilobar disease* (a) *Unilateral* If bronchiectasis is found in more than one lobe of the same lung in such combinations as the right middle and lower lobes, or the left lower and lingula of the left upper, double lobectomy or lobectomy and lingulectomy may be undertaken with little more risk than for single lobectomy. If all lobes of a lung are involved, total pneumonectomy may be offered. Here again, the risk of operation is perfectly respectable—certainly no more than 10 per cent and probably less than 5 per cent.

(b) *Bilateral* Bilateral lobectomy, in stages, is frequently performed for bronchiectasis. It is now considered routinely in planning the surgical program of suitable bilateral cases. Such combinations as both lower lobes, right middle and left lower lobes, right lower lobe and lingula of left upper lobe, or right lower and middle and left lower lobes have been repeatedly successfully treated by lobectomy in staged

operations. Even four-lobe disease (right middle and lower and left lower and lingula) has been, occasionally, successfully treated by excision. As might be expected, however, bilateral lobectomy is associated with considerably higher mortality since it subjects the patient to two major operations after the first of which he must convalesce with disease remaining in one or more lobes.

Nonsurgical—Although surgery is the treatment of choice in bronchiectasis, much can be done to palliate the distressing symptoms of the disease in patients who, because of age, general condition or other serious contraindications, must be denied the benefit of lobectomy or pneumonectomy. Some of these therapeutic measures are also of great value, as mentioned above, in preparing patients for surgery, when it must be postponed because of the excessive amount and foul character of the sputum, or because there has been an acute exacerbation of the pneumonitis that so frequently complicates bronchiectasis. In this category, lie postural drainage, bronchoscopy and penicillin inhalation.

1 *Postural drainage* is probably the most important single adjunct in the preoperative or palliative treatment of bronchiectasis. It may be carried out continuously or intermittently as indicated under Lung Abscess. To be effectual, it must be dependent in the sense that the mouth must be lower than the portion of the bronchial tree to be drained. This may be accomplished by hanging over the side of the bed or a table, or, if it is to be continuous, when the patient is confined to bed, the foot of the bed may be elevated. For ambulatory patients, it should be practiced in the morning on arising, before each meal and at bedtime. Faithfully carried out, it will usually result in a reduction of the amount and fetid character of the sputum.

2 *Bronchoscopy* The bronchoscopic aspiration of secretions at weekly intervals for a series of five or more treatments will frequently reduce, temporarily, the amount of the sputum and render it less foul. While in no sense curative, it is often distinctly beneficial to the inoperable patient, and is an aid in the preoperative preparation of patients, when surgery must be delayed because of copious foul sputum and/or a febrile state.

3 *Penicillin inhalations* While the inhalation of finely nebulized penicillin vapor is of too recent institution to be judged critically in a sufficiently large number of cases to be of statistical significance, there is evidence to suggest its value preoperatively and postoperatively and in cases of complicating pneumonitis. Inhaled from a special nebulizer in amounts of 20,000 to 50,000 units every three hours, we have observed that the sputum will lose its foul character within a few days to a week in the few cases with which we have had personal experience.

4 *X-ray therapy* has been advocated as a method of controlling the amount of sputum in inoperable patients. Our experience with this

form of therapy has been limited, but while we have observed temporary improvement in a few cases, there has always been recurrence. Riggins has pointed out the hazard of fibrosis and chronic indurative pneumonitis inherent in this method of treatment. We believe it has little to recommend it, and much to condemn it

LUNG ABSCESS

Lung abscess is a common disease but until the middle 1930's it was largely considered to be a medical problem, and the mortality ranged as high as 60 per cent, as reported by various clinics. While it is true that infected emboli lodging in the pulmonary circulation may result in abscess formation, it is now generally accepted that the typical putrid lung abscess is the result of the *aspiration* of the *proper* sorts of infected material. Thus, while the introduction of the ordinary pyogens into the bronchus of a dog will have no effect, the introduction of the scrapings from pyorrhea pockets from the human mouth containing a mixed flora of anaerobes, will result in the formation of putrid lung abscess with a high degree of frequency. Although perhaps 20 per cent of lung abscesses will result in spontaneous cures, the disease is now generally regarded to be primarily of surgical potential and should be so regarded from its inception.

Diagnostic Procedures—Sputum Examination—As in every instance of pulmonary disease in which there is sputum, this important secretion should be subjected to repeated examinations of concentrated pooled specimens for tubercle bacilli. Foul sputum may occur in rare cases of chronic cavernous pulmonary tuberculosis. On the other hand, occasional acid fast organisms may be present in the purulent secretions of a lung abscess, but it has been pointed out that this may represent sequestration of old healed foci of tuberculosis that chance to be in the field of pulmonary suppuration. Consequently, the findings of a few acid-fast bacilli once or twice in a series of examinations, while adding to the complexity of the problem, does not necessarily mean that the situation which must be met is not that of true lung abscess. It does mean, however, that the physician must be doubly alert in evaluating the evidence. A wide variety of other organisms, including most of the common mouth flora, is invariably present in the sputum. The anaerobic streptococcus is a constant finding and spirochetes and fusiform bacilli can usually be demonstrated in freshly collected specimens. Elastic fibers may be present indicating tissue destruction, but they are also present in the sputum arising from ulcerative lesions of the larynx and trachea.

Roentgenography—One of the most important diagnostic aids in lung abscess is the roentgenogram. By this means, the demonstration of a cavity with a fluid level in the apex of the lower lobe is of prime significance. For purposes of localization, therefore, exposures should

be made in the anteroposterior and lateral positions. Such a finding, with a surrounding zone of increased density, in the absence of tubercle bacilli in sputum which is foul, is strong presumptive evidence, although cysts, encapsulated empyema and certain bronchogenic cancers with necrotic centers may cast shadows indistinguishable from that of abscess. The technic of making the anteroposterior exposure with the patient reclining with the affected side uppermost, often serves to confirm the presence of a fluid level by making its direction parallel to the long axis of the body. Taking the roentgenograms early in the morning, before the patient has had an opportunity completely to evacuate the contents of the abscess cavity, is another method whereby fluid levels may be demonstrated.

As a matter of fact, only in about 50 per cent of cases can one demonstrate a cavity and a fluid level, which combination depends upon a patent communicating bronchus or, at least, air and pus in the cavity. In many instances, the cavity is filled with sequestrum or debris, or is obscured by the dense surrounding pneumonitis. Under these circumstances, recourse may be had to a series of laminograms to demonstrate the suspected cavitation.

During the early acute stage, a cavity may not be demonstrable since the process is essentially a pneumonic area which it resembles in the roentgenogram. Actually, the modern concept of the disease, which renders earlier drainage imperative, frequently leads to operation without positive roentgenographic evidence of cavitation.

On the not infrequent occasions when the abscess cavity is located in the apex of the lung, it may be differentiated from tuberculosis with great difficulty, although in these circumstances the physical signs of tuberculosis and the assiduous examination of the sputum for tubercle bacilli usually will aid in the differential diagnosis.

Bronchoscopy—Every case of lung abscess without exception must be examined bronchoscopically in order to rule out an obstructing neoplasm, stricture or foreign body as the cause of the abscess. The bronchoscopic examination also serves as a valuable localizing maneuver, since the bronchoscopist who should, preferably, be the thoracic surgeon, is frequently able to observe pus exuding from a particular bronchus which drains the suspected bronchopulmonary segment. While the older concept of drainage of a lung abscess bronchoscopically is now realized to be impossible of accomplishment, the bronchoscopist may temporarily improve drainage by shrinking down the swollen mucosal surfaces or actually removing obstructing granulations. Secretions may also be obtained directly from the bronchus for bacteriological study.

Bronchography—With the exception of the demonstration of a blocked bronchus leading to the suspected area, the introduction of iodized oil into the bronchial tree has been, in my clinics, of little definitive value in the diagnosis of lung abscess. If the abscess is acute,

oil will rarely, if ever, enter the abscess cavity. Certain chronic abscesses, with a patent communicating bronchus, may fill well. The value of the procedure, except in isolated instances, is dubious.

Aspiration—Attempts at needling the abscess cavity in acute putrid abscess are fraught with hazard, and mentioned only to be condemned. In such circumstances, aspiration can serve no useful purpose, and the danger of causing a putrid empyema is so great that the procedure should never be undertaken.

Treatment.—To Neuhof should go the credit of crystallizing the modern concept of lung abscess as being primarily a surgical disease, and of demonstrating that it may be safely treated in one stage with a mortality of about 2 per cent. With the diagnosis established, then, and definitive surgical treatment the aim, the policy followed in my clinics is to bring the patient to a successful operation at the earliest moment when it is demonstrated that the case under consideration is one that will not heal spontaneously. Procrastination is useless and hazardous in the great majority of cases.

With this in mind, all other forms of therapy should be considered tentative adjuncts until such a decision is arrived at.

Rest in Bed—Obviously all patients with acute lung abscess should be confined strictly to bed.

Postural Drainage—Patients who are raising sputum in any amount should take postural drainage unless the general condition is so poor as to contraindicate it. In order to be effectual, postural drainage is preferably undertaken in such a way as to be as continuous as possible. Thus, if the disease is in the lower lobes, the patient should lie continuously in the prone position with 12-inch blocks under the foot of the bed. Various devices have been evolved to facilitate continuous and intermittent postural drainage. Singer has invented a bed which may be adjusted to any position. For practical purposes, intermittent postural drainage is carried out at two-hour intervals during the day, and the patient is awakened once during the night. The patient must be carefully instructed in order that effectual dependent drainage is obtained. Putting the head over the side of the bed and coughing does not suffice. Frequently, the patient will discover a position which produces the best drainage in his particular case.

Continuous Oxygen—Since anaerobes play an important part in the symbiotic infection in lung abscess, it has been recommended that high concentrations of oxygen be administered continuously by means of a suitable well-fitted mask. Evaluation of this form of therapy is necessarily difficult, but the rationale seems reasonable. We have used it in only one case in which there was temporary improvement but eventual drainage. It deserves further trial.

Drugs—In the past, a wide variety of drugs has been employed in the treatment of lung abscess. The arsenicals, as used in the treatment of syphilis, have been extensively used while the sputum contained

spirochetes. However, it may be said that there has been no great preponderance of evidence in favor of one or another of these drugs. Recently the advent of penicillin has altered this aspect of the problem at least to some extent. We have observed 2 abscesses clear rapidly with vigorous penicillin therapy. We have observed two others regress and then become stationary and require drainage. In all cases, however, the sputum rapidly changed in character so that it was no longer foul. The drug should be administered intramuscularly in doses of 15,000 units every three hours, a total of 120,000 units each twenty-four hours, as long as improvement continues. It has also been recommended that penicillin be administered by the inhalation method using a special nebulizer actuated by oxygen. By this method, 20,000 to 50,000 units are inhaled in a fine mist every two or three hours, and it is stated that effectual blood levels are attained concomitantly by absorption from the pulmonary circulation. If this method is used, however, Anderson believes it should be supplemented by intramuscular penicillin as outlined above.

It is too soon to evaluate this form of therapy, but it should be used in all cases of lung abscess as soon as the diagnosis is made. Certainly there has been improvement in the general condition in every case we have observed. The pitfall will be to prolong its use after it is no longer effectual.

Operative Treatment—Many operative procedures have been employed with the development of thoracic surgery only to be discarded as their usefulness has been disproved. These include phrenic interruption, various packs and plombages, thoracoplasty and pneumothorax, the last being an extremely hazardous procedure with a uniformly high incidence of putrid empyema. Operative procedures in use today are discussed below.

1 *Bronchoscopy*—The diagnostic value of this maneuver has already been mentioned. The most bronchoscopy can offer as a therapeutic measure is temporarily to improve drainage by the removal of granulations and shrinkage of the mucosa. It can aid in the removal of inspissated secretions which the patient is unable to raise himself. It should not, however, be expected to effect a cure, nor should it be persisted in as a definitive form of therapy.

2 *Cavity drainage (pneumonotomy)*—As has been stated above, the old concept of waiting six weeks to three months for complete "localization" of a lung abscess before undertaking drainage has passed into limbo due largely to the writings of Neuhof. It may be stated didactically here that drainage, preferably in one stage, should be undertaken as soon as it is evident that the lesion is not improving clinically and by roentgenograms. Such a decision is usually taken in less than two weeks from the time treatment, as outlined above, has begun. A discussion of technic is not germane to this article. Suffice it to say that the operation is performed under local and regional anaesthesia and

in the hands of an experienced thoracic surgeon is not technical difficult Following early drainage, improvement is prompt and dramatic in the vast majority of cases Packing of the abscess cavity upon healing occurs is necessary, usually a matter of a few weeks

3 *Lobectomy and pneumonectomy*—In long-standing chronic abscess with extensive pulmonary destruction and associated secondary bronchiectasis total extirpation of the diseased lobe, lobes or lung offers the only hope of cure. While the mortality is somewhat high in this disease than for resections of the lobes or lung in bronchiectasis for example, it is steadily being lowered and with the use of penicillin promises to be a thoroughly feasible undertaking with a mortality perhaps under 10 per cent.

Complications.—*Empyema*—Perforation of the abscess which is most invariably peripherally located, extension of infection to the pleura, or ill-advised attempts at aspiration result in putrid empyema a common complication Promptly recognized and immediately treated by extensive rib resection and open drainage, a high recovery rate (90 per cent) may be expected Temporizing measures such as aspiration or closed drainage result in a much higher mortality (50 per cent)

Hemorrhage—Bleeding of varying degrees frequently occurs as complication of lung abscess due to the erosion or tearing of a vessel It is frequently fatal As a desperate measure, emergency lobectomy may be attempted If the abscess has already been drained, ligation and cauterization of the vessel or packing of the cavity usually will control the bleeding

Spread of the Infection—Intrapulmonary bronchogenic spread to the same or to the uninvolved lobes due to spilling of infected secretions is a complication resulting frequently in a fatal fulminating pneumonia or gangrene Penicillin has proved of value in this complication The complication will occur less frequently with early drainage

Cerebral Abscess—Metastatic spread of the infection to the brain by way of the vertebral veins is a not uncommon complication In our experience it has been invariably fatal Recently it has been recognized that ligation of the intercostal veins at the time of drainage of abscess is a necessary addition to the technic By this maneuver, the prevention of the spread of septic thrombi into the vertebral veins is accomplished

VITAMINS IN PRESENT DAY TREATMENT

HAROLD JEGHERS, M D , F A C P *

THERE appears to be a growing tendency to regard vitamin deficiency as synonymous with nutritional deficiency. This often leads to the erroneous concept that the treatment of any nutritional deficiency consists of the exhibition of one of the many multivitamin capsules or pills now so readily available. Such an approach overlooks the correction of the basic dietary habits responsible for the deficiency and further does not distinguish between the use of natural and complete vitamin substances in contradistinction to the use of a limited number of crystallized or concentrated pure vitamins. It is well to recall at this point that the vitamins now commonly used therapeutically constitute only part of the total vitamins known or still to be isolated and further that vitamins constitute only about a third of the forty or more nutrients required by the human body.

Nutrition is a relatively new and rapidly growing medical science. There is every reason to believe that the practical application of nutritional knowledge will play an ever-increasing role in the medical practice of the future. Its potentialities for preventive medicine appear enormous. There have been many pleas that the physician assume leadership in this field. The praiseworthy results of the application of nutritional principles in the practice of pediatrics are well known. There is much to be said for the continuation of these principles in the practice of adult medicine.

Proper nutrition has been accorded a place, along with heredity, in the control of longevity. The literature contains cautious suggestions that long-continued inadequacy of diet may be a factor in the early development of degenerative diseases. To be truly effective, proper dietary principles must be applied early and continued throughout life. It has been aptly stated that the practice of geriatrics commences where the practice of pediatrics leaves off. Any ill effects of a lifetime of incorrect diet cannot be righted, once old age is reached. The family doctor should make every effort to promulgate this thesis. It is earnestly suggested that an inquiry into a person's habits of eating and recommended dietary changes should be made a routine part of the annual health checkup now being widely recommended to the public.¹

The widening concept of deficiency disease to include deficiency of

From the Fifth and Sixth (Boston University) Medical Services, Boston City Hospital and the Department of Medicine, Boston University School of Medicine, Boston

* Associate Professor of Medicine, Boston University School of Medicine, Physician-in-Chief, Fifth Medical Service, Boston City Hospital, Assistant Physician, Clinical Staff, Evans Memorial, Massachusetts Memorial Hospitals

other nutrients than the vitamins and the application of this knowledge prophylactically as well as therapeutically constitutes at present the really intelligent approach to nutritional problems in present-day medical practice. Although this clinic is limited to the use of vitamins I trust that the broader aspects mentioned above will be constantly kept in mind.

CAUSES OF VITAMIN DEFICIENCY

Ordinarily vitamin deficiencies are caused by an inadequate diet, which results most commonly when the major caloric intake is in the form of refined foods such as white flour, sugar, lard and polished rice. Within recent years many of these refined foods have been nutritionally improved or enriched by the addition of one or more vitamins or minerals. It is well to realize that enrichment of food is not yet universal, that the number of nutrients added is limited, and that the enriched foods now available still do not equal natural foods in all respects.

One not uncommonly hears expressed at present the belief that full use of the program of enrichment of foods will ultimately lead to the complete disappearance of nutritional deficiencies and the need for any knowledge of these disorders. It is unlikely that such a utopia will ever be realized. Furthermore, many factors other than the use of refined foods may produce deficiency disease, and these will always be present as long as disease exists. The long-continued use of an unbalanced diet of even natural foods may eventually lead to deficiency of one or more nutrients. Alcohol, by supplying caloric energy but no vitamins, has been and will continue to be one of the commonest causes of deficiency disease. Therapeutic diets (such as elimination diets for allergic disturbances, diets for reduction of weight, for peptic ulcer and gallbladder disease) if not properly supplemented often are at fault. Numerous diseases by producing anorexia, vomiting or diarrhea interfere with proper food intake or its absorption. The liver is essential in the storage, conversion or utilization of almost every vitamin and disease of this organ invariably leads to vitamin deficiency. Fever, increased metabolism and physical exertion increase the need for certain of the B complex factors. Pregnancy, lactation and rapid growth during childhood and puberty all strikingly increase the need for nutrients as contrasted with more fixed requirements of grown adults. The water-soluble vitamins are lost during excessive perspiration or polyuria. Obstructive jaundice, sprue, intestinal fistulas and pancreatic disease interfere with vitamin absorption. Certain therapeutic agents such as alkali or mineral oil influence gastrointestinal absorption. There is growing evidence that some vitamins are synthesized in the gut and that use of drugs which affect the gastrointestinal flora may adversely affect this mechanism.² Likewise vitamin deficiency may result because of some defect in the metabolism of the vitamin within the body. This appears to be particularly true with regard

to vitamin A.⁸ Abnormality of vitamin metabolism is being shown with increasing frequency to be the responsible etiologic factor in a wide variety of hitherto unexplained disorders. This has been especially so with regard to certain skin disease. It is thus apparent that vitamin deficiency will be an ever-present problem in medical practice and apparently one destined to become more complex rather than more simple.

Dental Causes of Vitamin Deficiency—A much neglected phase of medicine is the causal relation of inadequate dentition to nutritional deficiency. This appears to be especially true in the elderly age group. Many older persons and occasionally those from younger age groups, have difficulty chewing solid food, especially meat, due to inadequate dentition. Pyorrhea, loose teeth, dental caries, extensive dental extractions, lack of artificial dentures or artificial dentures not used because of discomfort are common dental causes for vitamin deficiency. I have been strongly impressed with this factor in evaluating the cause of deficiency syndromes in patients studied on the medical wards and in the outpatient department of the Boston City Hospital. It is not uncommon to find patients who for months to years have eaten no meat or other solid foods requiring much chewing. Such persons should receive dental advice and an attempt made to correct this difficulty. If for any reason this is not possible, advice should be given with regard to soft or liquid foods that can be readily eaten but that will nevertheless be nutritionally adequate.

Ill-fitting dentures, aside from causing trouble in eating, may result in constant drooling of saliva. Over a period of time this results in angular fissures at the corners of the mouth, varying degrees of labial change and even glossitis. This syndrome is often mistaken for the changes produced by riboflavin deficiency, in fact Ellenberg and Pollock¹⁴ called it "pseudo-ariboflavinosis." Treatment with vitamin B factors is of no avail and only suitable dental treatment will result in improvement. The "pseudo-ariboflavinosis" is by no means a rare condition.

DIAGNOSIS OF VITAMIN DEFICIENCY

Recognition of vitamin deficiency depends on (1) a history of an inadequate diet or presence of some disease or physiologic disturbance interfering with full utilization of ingested food, (2) the presence of specific clinical symptoms and physical signs, (3) laboratory tests and (4) characteristic response to indicated vitamin therapy.

Laboratory Tests—On the whole there are but few specific laboratory tests for the recognition of vitamin deficiency. Furthermore, these procedures are complicated and but rarely available even in well equipped hospitals. Youmans and Patton⁴ have given a good discussion of them.

Impaired dark adaptation of the eyes as determined by a photom-

eter test and the lowered blood level of vitamin A and carotene may be indicative of vitamin A deficiency

Decreased urinary excretion of thiamine, niacin and riboflavin, particularly after a test dose, may be used to detect deficiencies of these water-soluble factors of the vitamin B complex. Blood pyuric acid level is often used as an indirect measure of thiamine deficiency. Vascularization of the cornea, as detected by use of the slit-lamp and corneal microscope, occurs in riboflavin deficiency but is nonspecific and produced by other means.

Lowered or absence of vitamin C in blood plasma, and particularly a diminution or absence of vitamin C from the platelet-white cell fraction of the blood, is highly diagnostic of vitamin C deficiency.

Decreased blood prothrombin level or increased prothrombin time indicates hypoprothrombinemia, this is indirectly indicative of vitamin K deficiency. Bleeding is likely to occur when the blood prothrombin level reaches 35 to 15 per cent of normal. This test is available in almost every hospital laboratory and should always be performed in persons manifesting any disturbance likely to interfere with the absorption of the fat-soluble vitamin K. These situations include prolonged high fever, neonatal period, chronic diarrhea, sprue, obstructive jaundice, liver disease and pancreatic disease.

Elevated serum phosphatase, diminution of blood phosphorus and specific changes in roentgenogram of bones are laboratory proof of rickets (vitamin D deficiency) in children.

Clinical Symptoms and Physical Signs.—Diets are complex and if deficient in one vitamin are likely to be deficient in others. As a result, long-continued use of deficient diets produces complex and multiple deficiency syndromes. Even when one clearly defined clinical syndrome seems to predominate, it is very likely that other deficiencies are present in subclinical forms. In fact, treating a recognizable syndrome with one pure vitamin with no change in the responsible inadequate diet may eventually allow the subclinical deficiencies to progress to a recognizable degree. It is well to recall also that a short period of severe vitamin depletion may produce a clinical picture quite different from the prolonged, but mild, depletion of the same vitamin. Furthermore, the clinical syndrome produced in children by any specific vitamin deficiency may be different from that produced in an adult.

It is impossible in a paper of this type to describe in detail the symptoms and signs of all the clearly delineated vitamin deficiency. These have been described numerous times^{5, 6} and no doubt all doctors have some journals, monographs or reference works to consult in this regard. The more clearly defined vitamin deficiency syndromes include night blindness, phrynodermia (hyperkeratosis follicularis), xerophthalmia, keratomalacia, Darier's disease, Wernicke's syndrome, peripheral neuritis, beri-beri heart disease, scurvy, vitamin P deficiency

pellagra, niacin deficiency encephalopathy, sprue, rickets, osteomalacia, ariboflavinosis syndrome, certain types of cirrhosis, and hemorrhagic hypoprothrombinemia. It has been my personal impression, based on observation of clinical material at Boston City Hospital for the past twelve years, that the above syndromes were more frequent five to ten years ago but are still seen with a fair degree of consistency, and that they are by no means limited to persons addicted to alcoholism. Furthermore, although the grosser degrees of vitamin deficiency have become rarer, milder and subclinical, vitamin deficiencies are still very prevalent. Unfortunately the members of this latter group are considerably more difficult to diagnose, and only by attention to clinical minutiae, a careful dietary history and prompt improvement with disappearance of clinical signs and symptoms following vitamin therapy can they be recognized.

Field and his associates⁷ have given an excellent account of the features of atypical and mild pellagra. Ruffin⁸ has discussed the recognition of early deficiency states. I have been particularly impressed with the appearance of the tongue as a key to the recognition of mild vitamin deficiency.⁹ The lingual papillae, especially the filiform papillae, appear to be sensitive to metabolic changes produced by vitamin deficiency, and tend to desquamate producing a tongue which is smooth and red in appearance. At times it is scarlet red and suggestive of niacin deficiency glossitis, or the papillae may be flattened and the tongue magenta in color, findings indicative of riboflavin deficiency. More commonly the tongue is simply smooth due to loss of papillae and beefy red in color, a condition designated as atrophic glossitis. Atrophic glossitis is frequently present in vitamin B complex deficiency, riboflavin deficiency, pellagra, pernicious anemia, Plummer-Vinson syndrome, sprue, pernicious anemia of pregnancy, chronic dysentery, intestinal stricture or fistula, infestation with broad fish tapeworm and achlorhydria. The presence of atrophic glossitis is an indication for therapy with liver extract or yeast. That the atrophic glossitis is often indicative of B complex deficiency is shown by the striking regeneration of papillae and restitution of the normal pinkish-white color of the tongue when proper therapy is instituted.

There are a wide variety of skin changes indicative of mild to severe vitamin deficiency. These have been discussed in detail elsewhere.³ Likewise, changes in the external membranes of the eye may give a clue to the diagnosis. Mild thiamine deficiency may resemble neurasthenia or chronic nervous exhaustion.¹⁰ With practice a surprising number of these clinical minutiae can be detected. After proper therapy is instituted disappearance of these minor clinical findings should be periodically searched for as this constitutes suggestive evidence of their deficiency origin.

Dietary History—A reliable dietary history is difficult to elicit, and is much neglected phase of history taking. The average physician feels much more competent to take a history and evaluate system com-

plants (e.g., cardiorespiratory) With practice, however, one can become equally adept at evaluating diets and the patient's nutritional status. Some knowledge of food and nutrition of course is essential but this can be readily acquired. There are numerous well written monographs and shorter treatises available on this subject. A knowledge of diet is useful not only in searching for deficiency disease, but in many other phases of medical practice (e.g., diabetes mellitus, obesity, underweight, nephritis and peptic ulcer). The development of potent therapeutic agents to control infectious diseases or endocrine disorders has tended to accentuate the search for better management of all types of metabolic disorders. It is therefore likely that diet and nutrition will receive an increasing interest by the research worker.

The following outline, used on the Boston University Medical Services at Boston City Hospital as part of the general history, is suitable for securing a reasonably satisfactory dietary history.

DIETARY HISTORY

Money spent per week for food		Regularity of meals	
No meals daily		Where eaten	
Highly seasoned foods		Idiosyncrasies of eating	
Use of following foods			
freely (F)	moderately (M)	rarely (R)	never (N) idiosyncrasy (I)
Meat	Milk		Potatoes
Pork	Buttermilk		White Bread
Liver	Cheese		Candy
Eggs	Ice Cream		Sugar
Fish	Puddings with Milk		Pastry
Soy beans			Refined cereals
			Rice
			Macaroni
			Spaghetti
Whole Wheat Bread	Butter		Green veg
Enriched Bread	Cream		Other veg
Whole cereals	Peanut butter		Citrus fruits
Beans	Other fats		Tomatoes
	Margarine		Salads
			Other fruits
Evaluate intake of diet with regard to following			
Excess (E)		Adequate (A)	Low (L)
Calories	Carbohydrate	Fat	Protein
Vitamin A	B ₁ C Niacin	Riboflavin	Minerals Ca Fe
Does patient take vitamin or mineral concentrates?			
Give a typical day's intake of food			
MORNING	NOON	EVENING	
Summary of positive findings			

Its use in conjunction with a set of tables giving the caloric value, as well as the carbohydrate, fat, protein, vitamin and mineral content of common foods in terms of household measurements (ounces, cups, teaspoons, slices [of bread], one item of food [e.g., one egg, one pat of butter] etc.) will enable the doctor to make a dietary estimate reliable enough for routine clinical use. Tables of food values are widely available and can be readily secured for reference. In 1941, the Committee on Foods and Nutrition of the National Research Council published its recommended daily allowances for the various dietary nutrients (the so-called "yardstick for good nutrition")¹¹ These recommendations have been accepted and widely publicized by many authorities on nutrition. Probably every physician has a copy of these recommended daily allowances for specific nutrients in his file since it has been reprinted frequently.

The patient's dietary history can be evaluated by comparison with this recommended daily allowance. Proper attention should be paid to factors likely to increase body metabolism, interfere with gastrointestinal absorption, increase vitamin loss, or impair liver function. Under such circumstances vitamin deficiency may result even though a theoretically adequate diet was eaten. Inquiries should be made concerning the amount of alcohol consumed. Alcoholic patients are especially likely to consume an inadequate diet.

Patients often have trouble remembering the details of their diet. With ambulatory patients not critically ill it is very helpful to have them keep a careful food diary (type of food, amount and how prepared) of all food eaten for a week and postpone the evaluation of their diet until the next meeting. They should be expressly cautioned against any change in their eating habits while under this survey. With patients admitted to a hospital, or with those critically ill and in need of immediate therapy such a plan is not feasible and one must depend entirely on the patient's story.

Inquiry should be made as to the amount of money spent per person per week for food and whether meals are eaten at home or in a restaurant. Smith¹² has given some excellent advice for those who eat away from home. The paper by Guy¹³ contains much practical advice with regard to diets. Idiosyncrasies of eating often are the cause of vitamin deficiency. There are many erroneous ideas concerning nutrition widely prevalent which need correcting. A typical example encountered recently was the housewife who separated the heavy cream layer from milk each day and discarded the skim milk portion because of the belief that all the nutrients in milk were contained in the cream layer. She was entirely unaware that the skim milk contained protein and minerals.

The dietary history form is arranged so that the first column lists foods rich in protein, the second foods rich in calcium, the third items high in carbohydrate, but poor in vitamins and minerals, the fourth

whole grains rich in vitamin B complex, the fifth foods rich in fats and lastly the vegetables and fruits. Persons who consistently avoid foods in any column except the third are more likely to develop a vitamin deficiency than those who select foods from each general group.

One must never fail to inquire whether the patient takes vitamin or mineral tablets, or capsules or concentrates as supplements to their diet. The patient must be impressed with the fact that the daily use of a vitamin capsule does not compensate for an inadequate diet. Correction of dietary habits is a more logical approach to this problem than attempts at elaborate supplementation to a basically poor diet. It is in this manner that physicians can counteract the prevalent belief that daily ingestion of a polyvitamin capsule makes any diet an adequate one.

TREATMENT OF VITAMIN DEFICIENCY

The principles of treatment of vitamin deficiency are relatively simple, and satisfactory therapeutic results usually follow rational use of the available methods or agents. Satisfactory treatment will, however, be conditioned by the accuracy of the clinical diagnosis and dietary history, and the ability to control underlying disease or physiologic conditions likely to interfere with absorption or metabolism of the diet and vitamins used.

Diet—The very essence of the control of any vitamin deficiency is the correction, if at all possible, of the dietary defect responsible for producing the deficiency. While this may not be essential for control of acute symptoms and signs it is essential if relapse is to be prevented in the future. Occasionally some disease exists which requires a special but unbalanced diet. Under such circumstances the unbalanced diet must be supplemented with natural vitamin concentrates of the proper kind and of potency sufficient to compensate for the dietary defect.

Vitamin A.—The recommended daily allowance of vitamin A for the adult is 5000 U.S.P. or international units. The majority of the capsules now available contain this dose. For special therapeutic purposes capsules containing 25,000 or 50,000 units are available. Vitamin A is indicated in the treatment of night blindness, xerosis and phrynodema. It is likely that either prolonged low grade vitamin A deficiency or some disturbance in the internal metabolism of this vitamin (dysvitaminosis A) may be the responsible etiologic mechanism for a variety of skin disorders. The literature contains claims³ that Darier's disease, pityriasis rubra pilaris, ichthyosis Sjörger's syndrome, dry skin, dryness and brittleness of hair, brittleness of nails, lichen spinulosus, verrux caseosa, keratosis blenorragica, callosities and acne may be in whole or in part produced by this mechanism. Its importance in Darier's disease appears to be best substantiated in this regard. For others of these, confirmatory studies are still awaited. Use of vitamin A for the treatment of hypertension and color blindness is not generally accepted.

Night blindness and xerophthalmia respond readily to moderate doses of vitamin A (10,000 to 20,000 units) continued for several weeks to two months or more. Skin lesions attributed to vitamin A deficiency or dysvitaminosis A for the most part respond slowly to therapy and require large doses orally (50,000 to 200,000 or more U.S.P. units per day) for months and perhaps years. When large doses are required, capsules of 25,000 or 50,000 units should be prescribed. Persons with dysvitaminosis A may require large doses of vitamin A to maintain improvement. Parenteral vitamin A therapy is but rarely indicated (e.g., in sprue, chronic diarrhea, obstructive jaundice, dysvitaminosis, celiac disease and pancreatic disease). Both bile and pancreatic lipase are necessary for its proper absorption.

B Complex Vitamins—The B vitamins include thiamine, riboflavin, niacin or niacinamide, pyridoxine, pantothenic acid, choline, inositol, para-aminobenzoic acid, folic acid, biotin and perhaps others. Although almost all of these are available commercially in synthetic form, only thiamine, riboflavin and niacin have well established uses in clinical practice. There is a growing but still controversial literature concerning the others.

Thiamine, riboflavin and niacin are prescribed by weight. The recommended dosage for therapeutic purposes should be at least several times the optimal daily requirement as recommended by the Committee on Foods and Nutrition of the National Research Council¹¹. For example, a 70 kg man, moderately active, needs 18 mg of thiamine, 27 mg of riboflavin and 18 mg of niacin daily. For gross deficiency of these vitamins, 10 to 30 mg of thiamine, 5 to 20 mg of riboflavin and 100 to 300 mg of niacin could be prescribed. Ordinarily these vitamins are given orally in daily divided doses. Where indicated they may be given parenterally. Parenteral preparations are commercially available which contain adequate amounts of thiamine, riboflavin, niacin, pyridoxine and calcium pantothenate. Niacinamide is commonly used in place of niacin (nicotinic acid) unless the vasodilator effect of the latter substance is specifically desired. The therapeutic dose of the B vitamin should be continued for one to several weeks or until the clinical deficiency is corrected, after which the amount required daily can be reduced to the optimal daily requirements.

While the synthetic B vitamins are indicated in the treatment of gross deficiency syndromes it is well to supplement the therapeutic regimen with one of the natural sources of the complete B complex. If the ordinary daily diet is to be supplemented, vitamin B complex in natural form is preferable to a capsule containing a limited number of the synthetic B vitamins.

Natural Sources of B Complex—There are a number of natural substances containing all the members of the vitamin B complex. These include liver extract, wheat germ, brewers' yeast, autolyzed yeast and

rice polishings. Wheat germ can be mixed with cereal. The vitamin content is listed on the package usually in terms of thiamine and riboflavin and from this one can judge the daily amount required.

Oral liver extract preparations are relatively expensive and are not commonly used as a source of B vitamins. Parenteral liver extract, however, is widely used for this purpose. It is commonly stated that crude liver extract (fewest U.S.P. units of antipernicious anemia factor per cubic centimeter) is a better source of the B vitamin than concentrated liver extract. The recent study by Clark¹⁶ would seem to indicate that both are comparable in their vitamin content. He found the averaged values of several concentrated liver extracts containing 15 units of antipernicious anemia factor per cubic centimeter was 0.55 mg. of riboflavin, 4.8 mg. of niacin and 1.97 mg. of pantothenic acid per 5 cc., while comparable preparations of crude liver extracts containing 2 units of antipernicious anemia factor per cubic centimeter contained 0.28 mg. of riboflavin, 4.13 mg. of niacin and 1.81 mg. of pantothenic acid per 5 cc. It is well to recall that the thiamine content of parenteral liver is negligible. Therefore, thiamine should be given in addition if liver extract is the main source of vitamin B complex therapy.

Autolyzed brewers' yeast is a good source of vitamin B complex. In our experience at Boston City Hospital it has been most acceptable to patients when given dissolved in boiling hot water. In this form it resembles beef bouillon. Dosage can be judged from the analysis on the container using the thiamine and riboflavin content as a guide.

Brewers' yeast, powdered or in tablet form, is probably the most satisfactory source of vitamin B complex for oral use. Potency varies with different brands. Many patients have trouble taking the number of tablets recommended and prefer the yeast powder instead. Spies⁸ has recommended its use in a mixture of 20 per cent dried brewers' yeast by weight and 80 per cent peanut butter. This is a palatable mixture. It is also commonly mixed in milk, chocolate milk shakes or malted milk shakes. The two following milk mixtures have been extensively used at Boston City Hospital in treatment of patients with nutritional deficiencies. They are particularly desirable for patients unable to chew solid food, for use during acute illnesses or to supplement other diets. The formula for the skim milk mixture as given makes a volume somewhat more than a quart, the use of 16 instead of 24 ounces of skim milk makes 1 quart. Mixing increases the final volume. The sodium chloride content is less than 2 gm. per quart. The mixture is flavored with chocolate syrup which is not included in the above calculations and adds slightly to the carbohydrate and fat. If desired, 1 to 4 teaspoonfuls of malted milk can be used with or in place of chocolate syrup as a flavoring agent. The orange juice in the mixture is readily accepted. If it is left out, ascorbic acid tablets should be prescribed as a supplement.

Fifteen grams of brewers' yeast powder is added to each quart of mixture. This amount gives no detectable taste, adds approximately 7.2 gm of protein and 5.8 gm of carbohydrate, and is generally accepted by patients.

FORMULA FOR SKIM MILK MIXTURE

	Carbohydrate	Protein	Fat
	Gm	Gm	Gm
6 oz orange juice	16.95		
4 oz Karo syrup	88.8		
6 egg whites		25.8	6
100 gm skim milk powder	38.8	35.4	1.7
24 oz skim milk	33.9	25.8	5.1
Total	178.45	87.0	7.4
Calories	1128		

The vitamin content of the skim milk mixture as given in the formula with added yeast powder is approximately 2.5 mg of thiamine, 1.8 mg of riboflavin, 6.5 mg of niacin, 1.5 mg of pantothenate, 0.6 mg of pyridoxine, 45 mg of ascorbic acid as well as other B complex factors. The vitamins except niacin and A and D, about equal the optimum daily allowances recommended by the National Research Council.

The protein is biologically highly active. The fat is low, but the amount of carbohydrate and the total calories are low in proportion to the amount of protein present. This mixture has been widely used for diets of patients with liver disease because of its high protein and carbohydrate and low fat content. It is very useful as a high protein-high vitamin supplement to the patient's routine diet.

FORMULA FOR WHOLE MILK MIXTURE

	Carbohydrate	Protein	Fat
	Gm	Gm	Gm
32 oz whole milk	45.2	34.4	32
100 gm skim milk powder	38.8	35.4	
3 whole eggs		18.0	18
Total	84.0	87.8	50
Calories	1137		

This mixture can likewise be supplemented with Karo syrup, orange juice, and brewers' yeast as described for the skim milk mixture and these add to the protein and carbohydrate value. Likewise it may be

flavored with chocolate or malted milk. Ascorbic acid tablets can be given to the patient if orange juice is not included.

Because of their low salt content these mixtures are suitable for the main source of nourishment and fluid for cardiac patients.

Other Vitamins—The use of ascorbic acid, vitamin D and vitamin K are well standardized and will not be discussed here.

THE PRESENT STATUS OF SULFONAMIDE THERAPY

FRANCIS C LOWELL, M D *

APPROXIMATELY six years have passed since the sulfonamide drugs became available for use on a scale sufficiently large to make clinical evaluation possible in a wide variety of diseases. During this period, new forms of sulfonamides have made their appearance from time to time, all of them, however, resembling each other in their mode of action and most of them differing principally in their solubility, their rate of absorption from the gastrointestinal tract and their rate of excretion by the kidney. All the commonly used sulfonamides are inhibited in their antibacterial action by para-aminobenzoic acid and to a variable extent by pus and necrotic tissue. These drugs also have in common the tendency to cause toxic reactions and careful supervision of the patient receiving a sulfonamide is necessary.

The biggest single change in the use of the sulfonamide drugs has been brought about by the advent of penicillin, which has recently become available for general use in this country. This can only be given by repeated injection at the present time, a fact which restricts its use and makes a sulfonamide the drug of choice under certain circumstances, even when penicillin may be more effective, and even though penicillin has the further advantage of producing very few toxic reactions.

With sulfonamides and penicillin available, the indications for serum treatment of infections due to such organisms as the pneumococcus and meningococcus are indeed rare. It is to be remembered, however, that gram-negative organisms, such as the influenza bacillus and Friedlander's bacillus, are entirely unaffected by penicillin and certain infections caused by them may best be treated with a sulfonamide and a specific antiserum.

The sulfonamides have been used for the prevention of recurrences of rheumatic fever and in the armed forces as a means of stopping or preventing epidemics of meningococcal and streptococcal infections. With proper control of the conditions under which the drugs are given, good results have been obtained with few and usually only mild toxic reactions. However, it seems unlikely that these measures can be effectively applied to civilians under the usual conditions of medical practice.

From the Evans Memorial, Massachusetts Memorial Hospitals and the Department of Medicine, Boston University School of Medicine.

* Assistant Professor of Medicine, Boston University School of Medicine, Associate, Evans Memorial and Assistant Visiting Physician, Massachusetts Memorial Hospitals.

ADMINISTRATION OF THE SULFONAMIDE DRUGS

In the treatment of an infection in which a sulfonamide is indicated it is probably wise to give the drug in *full therapeutic dosage*, as indicated, in the accompanying table. If the infection is so mild that smaller doses seem adequate, chemotherapy is usually unnecessary.

DOSAGE SCHEDULE FOR THE ADMINISTRATION OF THE SULFONAMIDE DRUGS TO ADULTS

Drug	Initial Dose		Maintenance Dose		Therapeutic Blood Levels, mg./100 cc.
	By Mouth	By Injection as a 0.5 to 5% Solution†	By Mouth	By Injection as a 0.5 to 5% Solution	
Sulfadiazine	4 gm.	5 gm.	1 gm. every 4 to 6 hours	2 gm. every 8 to 12 hours	8-15
Sulfamerazine			1 gm. every 6 to 8 hours	2 gm. every 12 hours	8-15
Sulfathiazole			1 gm. every 4 hours	2 gm. every 8 hours	4-8
Sulfapyridine			1 gm. every 4 hours	2 gm. every 8 hours	5-10
Sulfanilamide‡			1-1.5 gm. every 4 hours	3 gm. every 8 hours	8-15

The sodium salts of sulfadiazine, sulfamerazine, sulfathiazole and sulfapyridine should be used for parenteral administration. For subcutaneous injection the concentration of these should not exceed 1 per cent.

† Sulfanilamide is used as a 0.5-1 per cent solution for parenteral administration.

Exceptions to this are the treatment of mild urinary tract infections and the use of small doses of sulfonamide for prophylaxis in certain infectious diseases.

The *blood levels* of the various sulfonamide drugs which may be considered both safe and therapeutically effective are also shown in the table. Repeated determinations of the concentration of drug in the blood are necessary in order to insure satisfactory levels, and changes in dosage should be made if the level is too low or too high. In the presence of poor renal function the excretion of the sulfonamides may be delayed and the concentration in the blood may then reach high levels. When the concentration of a sulfonamide drug is determined, only the *free* or *unacetylated* form of the drug is measured in most laboratories. It is rarely necessary to determine the *acetylated* or *combined* form of the sulfonamide in the blood, except in patients with renal insufficiency who are given a sulfonamide for a prolonged period. Sulfanilamide and sulfapyridine are acetylated to a greater extent than the other sulfonamides.

Of the measures available for the prevention of toxic reactions to the sulfonamide drugs, the *administration of adequate quantities of fluid* is the most important. Sufficient fluid should be given to insure a urinary output in adults of 1500 cc. in twenty-four hours. In some patients, 2500 cc. of fluid daily will be sufficient, but patients with acute infections and fever may require 3000 cc. to 4000 cc. daily.

Fluids may be given orally in the form of soups, milk, fruit juices, normal saline and water or parenterally as saline, glucose and water in combination, so as to provide 10 to 15 gm of salt and a sufficient volume of fluid. In the presence of dehydration, the initial dose of sulfonamide should be accompanied by, or even preceded by, a sufficient quantity of fluid to insure hydration of the patient.

Renal Complications—Crystalluria, hematuria, renal colic, oliguria and anuria are complications of sulfonamide therapy, listed here in order of increasing seriousness. As renal complications are more frequent than any others during sulfonamide therapy, they should be watched for carefully. *Crystalluria*, that is, the finding of sulfonamide crystals in the spun sediment of freshly voided urine specimens, indicates that the conditions are present which predispose to renal complications and steps should be taken to increase the urinary output and to render the urine alkaline. The same may be said of *microscopic hematuria*. In neither instance is cessation of sulfonamide therapy necessary. *Gross hematuria, renal colic, oliguria and anuria* require immediate cessation of sulfonamide therapy followed as well by those measures just mentioned. In the presence of anuria, ureteral lavage with a warm alkaline solution may be indicated.

There is considerable evidence that the administration of alkali with a sulfonamide will reduce the tendency to those renal complications resulting from precipitation of the sulfonamide in the kidney. The base acts by raising the pH of the urine to 7 or higher, thereby increasing the solubility of the sulfonamide, especially the acetylated form, in the urine. Sodium bicarbonate may be given by mouth or sodium lactate (100 cc of one-sixth molar sodium lactate solution is equivalent to 1.4 gm of sodium bicarbonate) may be added to the solution of sulfonamide for parenteral administration. The amount of sodium bicarbonate necessary to raise the pH of the urine differs widely among patients and it is convenient and helpful to follow the urinary pH with nitrazine paper. In adults, an initial dose of 6 gm and a daily dose of 15 gm in twenty-four hours is usually sufficient. Patients who are nauseated and who are receiving a sulfonamide by mouth, may object to taking sodium bicarbonate in addition. Under such circumstances it may be wiser for the doctor to omit bicarbonate and to center his attention on insuring an adequate urinary output.

Severe renal damage during sulfonamide therapy may arise on some basis other than mechanical damage and obstruction due to precipitation of crystals. The pathogenesis of this complication is not clear. There develops tubular degeneration with increasing renal failure which may be fatal. The factors predisposing to this are not known but large dosage and high blood levels are not a sine qua non. The condition is characterized clinically by a decreasing urinary output, albuminuria, microscopic hematuria and white cells in the sediment.

Crystalluria may be absent. Treatment consists in the immediate cessation of sulfonamide therapy and the administration of fluids. Alkali may also be given but its effectiveness in this condition is unknown.

Other Toxic Reactions—*Rash and fever*, which may occur together or separately, are probably due to the development of an allergy to the sulfonamide. They are usually not serious reactions, but it is advisable to stop sulfonamide therapy when they occur. In certain individuals having eczematous skin eruptions which have been treated with prolonged local application of a sulfonamide, a very severe systemic reaction with rash and fever may develop rapidly after a sulfonamide is given by mouth or parenterally. Such reactions may be so severe as to endanger the patient's life. No simple reliable test for sulfonamide sensitivity has been devised. Skin tests have been described but their practical application at this time is still in doubt. The administration of a small dose of a sulfonamide (0.5 gm.) by mouth may cause, within a few hours, a rash, a rise in temperature, or both, in sensitive individuals, but tests of this kind may be hazardous.

Acute hemolytic anemia is a rare but dramatic complication occurring within one or two days of starting therapy. This reaction is dangerous and should be treated by (1) immediate cessation of sulfonamide therapy, (2) the administration of fluids and sufficient alkali to maintain the urinary pH above 7, and (3) transfusions as indicated by the degree of fall in the hematocrit or red count. A *slowly progressive anemia* is not uncommon during sulfonamide therapy. No treatment is required except transfusion if the anemia is marked. Sulfonamide therapy may be continued in the majority of cases.

A progressive *leukopenia* may develop slowly after several days of treatment. Where continued sulfonamide therapy is indicated, treatment may be continued unless (1) the percentage of polymorphonuclear cells falls below 50 per cent or (2) the total white count falls below 4000 with developing neutropenia. Daily white counts and smears should be made. Rarely, *agranulocytosis* develops, usually only after a week or more of treatment. In the face of this dangerous complication, sulfonamide therapy should be stopped. Secondary infection may be combated with penicillin, 15,000 to 20,000 units intramuscularly every three hours. Transfusion and pentnucleotide may also be given. In agranulocytosis arising from causes other than sulfonamide therapy the accompanying secondary infection may be treated with a sulfonamide if necessary in addition to penicillin.

INDICATIONS FOR SULFONAMIDE THERAPY

Before discussing individual diseases it should be emphasized that every attempt must be made to obtain as early as possible all the data and specimens necessary to make possible a definite bacteriologic diagnosis. When cultures are reported twelve to twenty-four hours later,

treatment may then be modified in the light of the bacteriologic findings. Grouping or typing of organisms should be carried out when possible.

Pneumonia—In view of the difficulty in distinguishing the bacterial pneumonias from primary atypical pneumonia (presumably caused by a virus), it seems advisable to treat all cases of severe or moderately severe pneumonia with chemotherapy at the outset. If after 48 to 72 hours of treatment there is no response and the clinical picture and bacteriologic findings indicate the absence of bacterial infection, chemotherapy may be stopped. The more severely ill patients should be hospitalized. Whether penicillin, sulfonamide, or both should be used will depend on the causative agent. If the cause is in doubt, especially if the patient is very ill, both penicillin and sulfonamide may be given.

It is to be noted that two important causes of pneumonia, the influenza bacillus and Friedlander's bacillus, are entirely unaffected by penicillin. Treatment here consists in full dosage of sulfadiazine or sulfamerazine and possibly the use of specific antiserum. This last is available for Friedlander's bacillus, type A and B, and for influenza bacillus, type B. The identification of types may be facilitated when it is recalled that the capsule of the influenza bacillus, type B, usually swells in the presence of type XXIX pneumococcus typing rabbit serum and often in the presence of type VI typing serum, and that of Friedlander's bacillus, type B, swells in the presence of type II pneumococcus typing rabbit serum. This information may be useful as pneumococcus typing serum is available in most laboratories.

Meningitis—The sulfonamide drugs are extremely effective in *meningococcic meningitis* and there is little reason at present to believe that penicillin alone would give better results. As the organism is highly sensitive to both drugs, combined therapy should be given to severely ill patients, especially those having a rash.

The treatment of meningitis due to the pneumococcus and streptococcus, organisms which are also susceptible to both sulfonamide and penicillin, consists in full dosage of a sulfonamide, preferably sulfadiazine, the intramuscular or intravenous administration of 200,000 units of penicillin daily and the intrathecal injection of 20,000 units of penicillin at twelve-hour intervals. Bacterial meningitis, especially pneumococcic, has a strong tendency to relapse when treatment is stopped, and for this reason treatment should be continued for at least ten days after culture of the spinal fluid has become negative, the sugar has returned to normal, and the cell count has fallen to 100 or less with a predominance of lymphocytes. Early diagnosis and treatment are of the utmost importance.

Pneumococcic meningitis still carries a high mortality and early intensive treatment is imperative. In addition to penicillin and sulfonamide therapy as outlined above, specific serum is available for the various pneumococcic types. If it is decided to give serum, this may

be given intramuscularly or intravenously in doses of 100,000 to 300,000 units after suitable precautions are taken. Serum should not be injected intrathecally. *Staphylococcic meningitis* requires prolonged treatment with both intramuscular and intrathecal penicillin and a sulfonamide in full dosage. *Staphylococci* are relatively insensitive to the sulfonamides and they vary greatly in their susceptibility to penicillin. Tests for the resistance of the infecting organisms to this drug are often helpful. Meningitis due to the *influenza bacillus*, which is unaffected by penicillin, requires prolonged treatment with full doses of sulfadiazine, sulfamerazine or sulfapyridine. Therapeutic rabbit serum for type B infections is available.

Genitourinary Infections—The colon bacillus which is penicillin-resistant, is the common cause of urinary tract infections and for this reason a sulfonamide drug especially sulfathiazole or sulfadiazine, is indicated. Small doses 0.5 gm three times daily, will frequently control mild infections, but in more severely ill patients full doses of the drug should be given. Sulfamerazine should be less effective, on theoretical grounds, because it is excreted less rapidly by the kidney. Penicillin may be used when a susceptible organism, such as the staphylococcus, is causing the infection.

Numerous instances of infection with sulfonamide-resistant strains of gonococcus are encountered in medical practice and, at the present time, penicillin is the drug of choice in gonorrhea. Clinical cure is achieved in a very high proportion of uncomplicated cases when a total of 100,000 units of penicillin is given intramuscularly in five doses of 20,000 units at three hour intervals. However, more prolonged treatment is often necessary in the presence of prostatitis, vesiculitis, arthritis and other complications. Syphilis and gonorrhea may occur together. In this event the short treatment of gonorrhea with penicillin may lead to much difficulty in the diagnosis of syphilis later.

Dysentery—Sulfadiazine appears to be the drug of choice in the treatment of dysentery. The drug should be given in full dosage and continued for a period of four days after cultures of the stools are negative for the infecting organism. Special care should be taken to provide a large fluid intake in order to insure an adequate urinary output.

THERAPEUTIC FAILURES

The nature and severity of the infection at the time treatment is started greatly influences the response to treatment and the incidence of complications. Difficult problems are presented by patients who appear to have an infection of a type which ordinarily responds readily to therapy, but who fail to improve after several days of therapy. A number of causes for such failure should be considered.

Inadequate blood levels of a sulfonamide may be present in patients receiving full therapeutic doses by mouth but in whom absorption from the gastrointestinal tract is slow. Also, certain patients may ex-

crete the drug in the urine more rapidly than others. The only way to recognize this difficulty is to make repeated determinations of the blood level. The dosage of drug may be increased until satisfactory levels are obtained. Patients receiving a sulfonamide by mouth who fail to attain adequate blood levels may be given supplementary doses of two or more grams intravenously.

The development of *sensitivity* to a sulfonamide drug, usually occurring after five or more days of treatment, may cause the persistence of fever and thus simulate a therapeutic failure. If a rash also appears, the correct cause of the fever is readily suspected, but in the absence of any skin manifestations there are no definite criteria by which one can recognize the condition. If drug fever is present, a fall in temperature follows cessation of therapy. This fall is rapid in patients who have been receiving sulfathiazole, occurring in twelve to twenty-four hours, but the fall is more delayed in the case of sulfadiazine and sulfamerazine where the rate of excretion is slower.

Occasionally the infecting organism is a *sulfonamide-resistant* strain. Larger doses or a different sulfonamide may be tried but usually little is gained in this way. Penicillin should be given if the organism is susceptible to this drug.

Pathogenic organisms are often present in the throat or elsewhere even though they may be playing no part in the patient's infection. This is a common source of *error in diagnosis* and when the correct cause of the infection is found, more effective treatment can often be given.

Patients who have a *complication*, such as empyema, abscess, osteomyelitis or endocarditis, may continue to have fever and leukocytosis in spite of intensive therapy. Renal infections associated with *stone* or *congenital defects* may also respond poorly to therapy. Treatment of the local condition is usually required before complete recovery will take place.

SUMMARY

The sulfonamide drugs are best given in full therapeutic doses in the treatment of most acute infections. Repeated determinations of the blood level are necessary in order to insure safe and adequate treatment. Toxic reactions must be recognized early.

The present-day treatment of many infectious states can be extremely effective when the cause and severity of the infection are known and when appropriate treatment is started early.

ERRATUM

In "The Use of Electrocardiograms in Medicine" by Harold M. Stewart, M.D., appearing in the May number the first paragraph on page 600 should read "In Figure 106 are shown the records of a patient who had electrocardiographic evidence of posterior base lesion and one year later evidence of anterior base lesion. He died shortly after this last accident. At autopsy the scar of the first myocardial infarction was seen involving the basal region and the fresh infarction involving the apex of the heart."

LABORATORY FINDINGS IN THE BLOOD AND URINE IN HEALTH AND DISEASE

STANLEY E BRADLEY, M D *

As medical knowledge expands, the position of the laboratory in every field of medical practice becomes increasingly important. Its services are indispensable in modern diagnosis and treatment, particularly since chemotherapeutic methods of halting disease processes and of repairing the ravages of disease have proved their worth and come into universal use

The large number of procedures carried out in the routine laboratories of even small hospitals each year is indicative of this importance, but it is also indicative of misuse. It is apparent everywhere that many physicians use laboratory facilities unthinkingly. Laboratory studies are often demanded routinely on a hit-or-miss basis in the hope of easy diagnosis, frequently with the aim of impressing and pleasing the patient. This is unfortunate because it results in unnecessary labor in the face of manpower shortages, in a deterioration of standards and in unreasonable expense. In the last analysis, diagnosis devolves upon the physician, depending upon his observational skill and his perception of significant facts in data culled from the history, the physical examination, and, finally, the laboratory study. This task can never be safely shifted to the shoulders of laboratory personnel. On the other hand, there is abundant evidence that available facilities are not used efficiently. Not infrequently, intuition plays too large a role in guiding treatment. This is to be deplored because the accurate adjustment of chemotherapy requires an accurate knowledge of the system under treatment.

One important cause of these abuses lies in the staggering number of procedures now available and in the difficulty of keeping in mind the normal figures and causes of deviations. The tables that follow have been compiled with the purpose of providing for ready reference the range of normal values of a large number of blood and urine constituents. A list of some of the more important disorders in which changes are observed has been added. The tables are based on the physiological systems of the body that are disturbed by disease. It can be seen that a view of these data as primarily expressive of physiological states rather than of etiological factors is implicit in this arrangement. It is true that certain tests may be of great value in clari-

From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston

* Instructor in Medicine, Boston University School of Medicine, Assistant Physician, Evans Memorial, Massachusetts Memorial Hospitals.

fying and defining causation but, by and large, the data tabulated here express what is *happening* in the body, not what is *causing* the disturbance.

On the whole, a policy of generalization has been followed. Thus such general expressions as diarrhea, vomiting and renal insufficiency and the like are used where possible. All renal diseases leading to renal insufficiency or nephrotic syndrome are to be considered as implicated under those headings. It should be understood, moreover, that these findings are not always found in the disorders listed, many, such as diabetes mellitus, show no derangement of electrolyte balance until severe changes such as ketosis and coma have set in. Abbreviations are defined in the text of the tables or are conventional. In addition, the following symbols are used (+) increased in, (—) decreased in, (N) normal or unchanged in, (B) concentration in whole blood, and (P) concentration in plasma.

Concentrations are given in terms of serum or plasma volume. No effort has been made to separate the two because the differences are insignificant for practical purposes. Proteins of course, are stated in terms of plasma concentration.

More exhaustive consideration of pathological alterations and details of the various procedures should be sought in the sources that have been freely drawn upon in the construction of the tables.

(-) Insulin sensitivity hyperinsulinism.	
Glucose Tolerance Test (oral)	
Hyperglycemic response—Diabetes mellitus, starvation hyperthyroidism, hyper- pituitarism (acromegaly, etc.), myasthenia gravis, Cushing's syndrome.	

Hypoglycemic response—Hypothyroidism, hypopituitarism, Addison's disease, steatorrhea, diarrhea

Glucose Tolerance Test (intravenous)

Hyperglycemic response—As in oral

Hypoglycemic response—As in oral except that steatorrhea and diarrhea have no effect on curve

Insulin Tolerance Test

Insulin resistance—(delayed or absent fall)—Cushing's syndrome, hyperpituitarism (acromegaly, etc.) Insulin resistance of unknown etiology

Hypoglycemic unresponsiveness—(delayed or absent terminal rise)—Hypoparathyroidism, Addison's disease, hypopituitarism

Lipase

(+) Pancreatitis, pancreatic neoplasm

Diastase

(+) Acute pancreatic disorders (trauma, pancreatitis, etc.), mumps

Congo Red Test

Less than 70 per cent of dye in blood after 30 minutes—amyloidosis, massive proteinuria

Phosphatase—acid

(+) Carcinoma of prostate

Phosphatase—alkaline

(+) Neoplasm of bone, Paget's disease of bone, fragilitas ossium, rickets, osteomalacia, hyperparathyroidism, biliary obstruction

Creatinine

(+) Renal insufficiency (except when acute or upon obstructive basis)

Creatine

(+) Renal insufficiency

Creatine Tolerance Test

Increased retention—Hypothyroidism, myotonia congenita

Decreased retention—Hyperthyroidism, myotonia atrophica, progressive muscular atrophy

"Hormonal" Iodine

(+) Hyperthyroidism, hyperpituitarism (acromegaly, etc.)

(-) Hypothyroidism, hypopituitarism

17-Ketosteroids

(+) Adrenal cortical carcinoma, adrenal cortical hyperplasia, testicular interstitial cell tumor

(-) Hypothyroidism, hypopituitarism, Addison's disease

Chorionic Gonadotropin—A-Z Test—positive

Pregnancy, hydatid mole, chorionepithelioma

Nonprotein Nitrogen and Urea Nitrogen

(+) Renal insufficiency, hyperthyroidism, shock, hemorrhage, fever, vomiting, diarrhea, cardiac decompensation, dehydration, pregnancy

Urea Nitrogen

(-) Starvation, diuresis, acute yellow atrophy

Uric Acid

(+) Renal insufficiency, gout, toxemia of pregnancy, leukemia

Ketone Acids

(+) Diabetes mellitus, starvation, alkalosis, vomiting

Lactic Acid

(+) Extreme exertion, cardiac decompensation, shock, diabetes mellitus

Pyruvic Acid

(+) Thiamine deficiency, cardiac decompensation, fever, diabetes mellitus, hyperthyroidism

Phenols

(+) Renal insufficiency, intestinal obstruction, pernicious anemia

Ammonia

(+) Renal insufficiency

Amino Acid Nitrogen

(+) Acute yellow atrophy, occasionally renal insufficiency, leukemia

(-) Nephrotic crisis

Guanidine

(+) Renal insufficiency

Vitamins

(-) Dietary deficiency, fever, diarrhea, steatorrhea, hepatic disease, wasting disease.

Icterus Index

(Up to 20—subclinical jaundice) Jaundice, carotinemia.

Bilirubin (quantitative)

(+) Jaundice—indirect (+) in proportion to direct—hemolytic jaundice, direct (+) in proportion to indirect—obstructive, hepatotoxic jaundice (less marked disproportion)

Cholesterol

(+) Hypothyroidism, biliary obstruction, cirrhosis, diabetes mellitus, nephrotic syndrome, renal insufficiency, hypercholesterolemic lipoidoses (xanthomatosis), cardiac disease

(−) Renal insufficiency, any extensive hepatic disease, hyperthyroidism, fever, cachexia, steatorrhea, anemia.

Neutral Fat and Fatty Acids

(+) Hypothyroidism, anemia, diabetes mellitus, nephrotic syndrome

(−) Hyperthyroidism

Lipoid Phosphorus

(+) Diabetes mellitus, nephrotic syndrome

(−) Anemia

* The multiplicity of liver function tests renders complete tabulation impossible. Only the more reliable and commonly used procedures are listed.

4 RENAL FUNCTION TESTS

IN HEALTH

Clearance Tests

Inulin Clearance	Glomerular Filtration Rate (GFR)	Male	110–150 cc./min
Mannitol Clearance		Female	105–132 cc./min
Diodrast Clearance	Renal Plasma Flow (RPF)	Male	560–830 cc./min
P - aminohippurate Clearance		Female	490–700 cc./min

Filtration Fraction (FF) (equals GFR/RPF)

Male	17–21 per cent
Female	17–23 per cent
Standard	40–65 cc./min
Maximal	60–100 cc./min

Urea Clearance (Cu)

Male	300–450 mg./min
Female	250–350 mg./min

Maximal Glucose Reabsorptive Capacity (TmG)

Male	43–59 mg./min
Female	33–51 mg./min

Maximal Diodrast Excretory Capacity (TmD)

40–60 per cent in first hour,	
60–85 per cent in second hour	

Phenolsulfonphthalein Excretion

1 004–1 025

Dilution-Concentration Test

IN DISEASE

GFR	(−)	Glomerulonephritis, nephrosclerosis, and other renal diseases, shock, anemia.
RPF	(+)	Fever, certain cases of acute diffuse glomerulonephritis.
RPF	(−)	Glomerulonephritis, nephrosclerosis, and other renal diseases, shock, anemia, apprehension, pressor drugs
FF	(+)	Essential hypertension, nephrosclerosis, pressor drugs
FF	(−)	Glomerulonephritis, fever, orthostasis, shock, anemia.
Cu	(+)	Fever, rising slope of diuresis curve, after protein meal.
Cu	(−)	Renal disease in which filtration is impaired, oliguria, shock, anemia
TmG	(−)	Tubular damage, (TmG also reduced by obliteration of glomeruli), any extensive renal disease
TmD	(+)	Fever, diuresis
PSP	(−)	Any extensive renal disease
Dilution, Concentration	—Reduced range—tubular damage by any extensive renal disease	

5 THE CONSTITUENTS OF THE URINE

IN HEALTH

	Grams per 24 Hours		Grams per 24 Hours
Water	1000-1500 cc.	Sodium	3 0-5 0
Total Solids.	55 0-70 0	Potassium	1 5-2 5
Specific Gravity	1 002-1 040	Calcium	0 1-0 3
pH	4 8-7 8	Magnesium	0 1-0 3
Urea	25 0-35 0	Iron	0 1-0 2
Creatine	0 0-0 06	Chloride	10 0-15 0
Creatinine	1 2-1 7	Iodine ('Hormonal ') adult	20-70 gamma
Amino Acids	0 2-0 4	child	20-35 gamma
Hippuric Acid	0 1-1 0	Sulfur--total.	2 0-3 4
Lactic Acid	20 0-80 0	Inorganic	1 7-2 7
Oxalic Acid	0 01-0 02	Ethereal	0 1-0 3
Uric Acid	0 2-0 8	Neutral	0 2-0 4
Purine Bases	0 01-0 06	Phosphate	2 5-3 5
Allantoin	0 005-0 015	Urobilin	0 01-0 13
Indican	0 005-0 01	Porphyrius	0-30 gamma
Phenols.	0 1-0 3	Thiamine.	30-300 gamma
Ammonia Nitrogen	0 5-1 0	Riboflavin	500-800 gamma
Total Reducing Substances	0 5-1 5	Nicotinic Acid	3-10 mg
Ketones	0 3-1 0	Ascorbic Acid	15-50 mg
		Hormones--See Table 2	

IN DISEASE

Water	(+) Diuresis, excess intake, diabetes insipidus, renal insufficiency
	(-) Dehydration, shock, urinary obstruction, nephrotic syndrome
Total Solids and Specific Gravity	(+) Dehydration, diabetes mellitus, cardiac decompensation
pH	(-) Renal insufficiency, diabetes insipidus, diuresis.
	(+) Diuresis, alkalosis, hyperventilation, after meals.
Urea	(-) Oliguria, acidosis, shock, urinary infection
	(+) Diuresis, high protein intake, starvation.
	(-) Renal insufficiency, cardiac decompensation, shock, urinary obstruction, oliguria, dehydration, low protein intake, acute yellow atrophy
Creatine	(+) Hyperthyroidism, in childhood, starvation, cardiac decompensation, myositis (trichiniasis, dermatomyositis, etc.) high creatine diet, progressive muscular dystrophy, myotonia atrophica, amyotonia congenita, myasthenia gravis, progressive muscular atrophy
Creatinine	(-) Myotonia congenita.
	(+) Familial periodic paralysis.
Amino Acids	(-) Renal insufficiency myotonia congenita.
	(+) Cystinuria, histidinuria, tyrosinuria.
Hippuric Acid	(-) Renal insufficiency
Lactic Acid	(-) Renal insufficiency any extensive hepatic disease.
	(+) High carbohydrate diet, exercise, anoxemia, pneumonia, dyspnea, anesthesia.
Oxalic Acid	(+) Increased dietary intake (rhubarb, etc.)
Uric Acid	(+) Increased purine intake, exercise, pregnancy labor, during acute episode of gout, toxemia of pregnancy
Purine Bases	(-) Starvation gout (between acute attacks) renal insufficiency
Allantoin	(+) Increased purine intake.
Phenols	(-) Renal insufficiency
	(+) Drugs, intestinal obstruction, renal insufficiency

Ammonia	(+)	Pregnancy, toxemia of pregnancy, vomiting, diarrhea, dehydration, acidosis, urinary infection by urea-splitting organisms
	(-)	Renal insufficiency
Total Reducing Substances	(+)	Glycosuria in diabetes mellitus, Cushing's syndrome, renal diabetes, chronic or acute pancreatitis, pernicious anemia, pregnancy, severe pyogenic infection, pentosuria, lactosuria
Ketones	(+)	Alkalosis, starvation, prolonged vomiting, diarrhea, diabetes mellitus
Sodium	(+)	Diuresis, renal insufficiency, Addison's disease, after meals
	(-)	Sweating, renal insufficiency, diarrhea, vomiting, dehydration, anesthesia, pneumonia, diabetes mellitus, Cushing's syndrome, cardiac decompensation, nephrotic syndrome
Potassium	(+)	Diuresis, dietary increase, drugs, renal insufficiency, family periodic paralysis, Cushing's syndrome
	(-)	Addison's disease, renal insufficiency, dehydration
Calcium	(+)	Hyperparathyroidism, excess vitamin D intake, diuresis, acidosis
	(-)	Renal insufficiency, hypoparathyroidism, hyperthyroidism, steatorrhea, diarrhea, vitamin D deficiency
Magnesium	(+)	Acidosis
	(-)	Hyperphosphatemia, high fat intake, alkalosis, hyperparathyroidism
Iron	(+)	Hemachromatosis, hematuria, hemoglobinuria
Chloride	(+)	Renal insufficiency, diuresis, high chloride intake, acidosis, Addison's disease
	(-)	Starvation, dehydration, diarrhea, vomiting, after meals, sweating, prolonged hyperventilation, anesthesia, alkalosis, fever, cardiac decompensation, renal insufficiency, pernicious anemia, Cushing's syndrome
Iodine	(+)	Hyperthyroidism
	(-)	Hypothyroidism
Sulfur	(+)	Cystinuria, acute yellow atrophy, melanuria
Ethereal Fraction	(+)	Phenol ingestion, intestinal obstruction
Phosphate	(+)	Acidosis, hyperparathyroidism, hyperthyroidism, vomiting
	(-)	Hyperinsulinism, renal insufficiency, hypoparathyroidism, hypothyroidism, pregnancy, anesthesia
Urinary Pigments—Porphyrins	(+)	Acute porphyria, excess intake of veronal, sulfonal, etc., congenital porphyria, hepatic disease, pernicious anemia, hemolytic anemia, hemoglobinuria
Vitamin	(-)	Renal insufficiency and dietary deficiency

6 RESPIRATORY DATA

IN HEALTH

Blood Gases

Arterial

Oxygen Content	16-20 vol per cent	pO ₂ 95-100 mm Hg
Oxygen Hemoglobin Capacity	17-21 vol per cent	
Oxygen Content/Oxygen Capacity	95-97 4 per cent	
Carbon Dioxide Content	49 6-54 4 vol per cent	pCO ₂ 40 2-47 2 mm Hg
Carbon Dioxide Content (T40)	48 3-52 9 vol per cent	
Carbon Monoxide	0 1-0 5 vol. per cent	

Venous

Oxygen Content	11 0-16 9 vol per cent	pO ₂ 30-50 mm Hg
Oxygen Content/Oxygen Capacity	60-35 per cent	
Carbon Dioxide Content	55-74 vol per cent	pCO ₂ 37-58 mm Hg
Carbon Dioxide Content (T40)	43 3-55 9 vol. per cent	

Respiratory Gases	
Alveolar Air	
Oxygen	13.5-15.5 vol. per cent pO_2 95-110 mm. Hg
Carbon Dioxide	5.3-6.3 vol per cent pCO_2 38-45 mm. Hg
Carbon Dioxide Output	87-117 cc./min /square meter surface area
Oxygen Absorption	120-145 cc /min /square meter surface area
Ventilation	2.5-3.9 L./min /square meter surface area
Vital Capacity	
Male	4000-5700 cc.
Female	2300-3900 cc.
Basal Metabolic Rate	\pm 10 per cent of mean standard

IN DISEASE

Arterial

Oxygen Content

- (+) Polycythemia.
- (-) Anemias, high altitude, pulmonary edema, emphysema, bronchial asthma, pneumonia, pneumothorax, congenital heart disease.

Oxygen Capacity

- (+) Polycythemia.
- (-) Anemia, carbon monoxide poisoning, methemoglobinemia

Oxygen Saturation

- (-) High altitude, pneumonia, respiratory obstruction, pulmonary edema, congenital heart disease.

Carbon Dioxide Content

- (+) Pneumonia, respiratory obstruction, pulmonary edema, congenital heart disease, emphysema. [See Table 1— HCO_3 (+)]
- (-) Hyperventilation. [See Table 1— HCO_3 (-)]

Venous

Oxygen Content and Oxygen Saturation

- (+) Hyperventilation fever hyperthyroidism
- (-) High altitude, pneumonia, respiratory obstruction, pulmonary edema, congenital heart disease, cardiac decompensation, anemia, carbon monoxide poisoning methemoglobinemia, shock, cold, exercise.

Carbon Dioxide Content

- (+) (See arterial carbon dioxide content) cardiac decompensation shock, cold
- (-) (See arterial carbon dioxide content.)

Respiratory Cases

Alveolar Oxygen

- (-) High altitude.

Alveolar Carbon Dioxide

- (-) Hyperventilation.

Carbon Dioxide Output

- (+) Increased R. Q. or metabolism, acidosis.
- (-) Alkalosis, decreased R.Q. and metabolism.

Oxygen Absorption

- (+) Increased total metabolism, see B.M.R.
- (-) Decreased total metabolism.

Ventilation

- (+) Exercise fever acidosis, post-encephalitic and hysteric hyperventilation head injury high altitude
- (-) Alkalosis, morphinism.

Vital Capacity

- (+) Orthostasis.
- (-) Cardiac decompensation pulmonary edema, pneumothorax, hydrothorax and other extensive intrathoracic processes, respiratory obstruction

- B.M.R. (+) Excitement, psychoneurosis, fever hyperthyroidism caffeine, polycythemia, leukemias, cardiac decompensation.
- (-) Starvation hypothyroidism, shock, edema, hypopituitarism.

7 HEMATOLOGICAL DATA

IN HEALTH

Blood Cytology

Total leukocytes		7,000-10,000 cells/cu. mm
Myelocytes		0
Juvenile neutrophils		3-5 per cent
Segmented neutrophils		54-62 per cent
Eosinophils		1-3 per cent
Basophils		0-1 per cent
Lymphocytes		25-33 per cent
Monocytes		3-7 per cent
Platelets		250 000-400,000/cu mm
Red blood cells	male	4,600,000-6,200,000 cells/cu. mm
	female	4,200,000-5,400,000 cells/cu mm
Reticulocytes		0-2 per cent

Hemoglobin	male	14 0-18 0 gm per 100 cc.
	female	12 0-16 0 gm per 100 cc.
Volume, packed cells (hematocrit)		
	male	40 0-52 0 cc. per 100 cc.
	female	37 0-47 0 cc. per 100 cc.
Mean Corpuscular Volume		82 0-92 0 c μ
Mean Corpuscular Hemoglobin		27 0-31 0 $\gamma\gamma$
Mean Corpuscular Hemoglobin Concentration		32 0-36 0 per cent
Mean Corpuscular Diameter		7 2-7 8 μ
Erythrocyte Fragility Test		
	Slight hemolysis	in 0 45-0 39 per cent sodium chloride
	Marked hemolysis	in 0 42-0 36 per cent sodium chloride
	Complete hemolysis	in 0 33-0 30 per cent sodium chloride
Erythrocyte Sedimentation Rate		
	Wintrobe	0-15 mm /hour
	Westergren—male	1-3 mm /hour
		3-7 mm./hour
	female	0 1-0 4 mm./min
	Rourke-Ernstene	
Bleeding Time		1-3 min
Coagulation Time		2-10 min
Retraction Time of Blood Clot		1 hour
Prothrombin Time (Quick)		12-14 seconds (60-120 per cent of normal)
Capillary Fragility Test		10-15 petechiae/sq in on forearm, 5 cm below elbow, after 10 min cuff pressure on arm at 90 mm Hg

Bone Marrow Cytology

Per Cent

Granulopoietic Series	
Myeloblasts	0 3-5 0
Promyelocytes	1 0-8 0
Myelocytes—neutrophilic	5 0-19 0
	eosinophilic
	0 5-3 0
	basophilic
	0 0-0 5
Metamyelocytes ("juvenile forms")	13 0-32 0
Polymorphonuclear neutrophils	7 0-30 0
	eosinophils
	0 5-4 0
	basophils
	0 0-0 7
Lymphocytes	3 0-17 0

7 0-32 0

IN DISEASE

Total Leukocytes (usu ally neutrophils) (+) Acute infections, hemorrhage at birth labor vomiting poisonings, renal insufficiency diabetes mellitus, gout, leukemia.

(-) Certain infections (typhoid virus and protozoal infections) overwhelming infection or toxemia cachexia, Banti's syndrome.

(+) Allergy, skin diseases, parasitic diseases, scarlet fever, chorea, pernicious anemia, myelocytic leukemia.

(+) Chronic myelocytic leukemia, Hodgkin's disease, chicken pox, smallpox.

(+) Certain infections (pertussis, infectious mononucleosis, exanthemas tuberculosis) lymphocytic leukemia.

(+) Certain infections (tuberculosis, typhus, many rickettsial and protozoal [malaria, trypanosomiasis] infections), monocytic leukemia, tetrachlorethane poisoning kala azar

(+) Appear in leukemias particularly myelocytic leukemia.

(+) Rheumatic fever acute suppuration, fractures, hemorrhage chronic myelocytic leukemia, Hodgkin's disease, erythremia.

(-) 'Primary' thrombocytopenic purpura, certain chemicals (arsenicals, sodium benzol, gold salts), leukemias, severe anemias and infections, Banti's and Gaucher's diseases.

(+) Appear in hemolytic anemia pernicious anemia during treatment.

(+) MCHC (N) Macrocytic anemia, pernicious anemia, carcinoma of stomach neoplastic invasion of bone marrow (myelophthisic anemia) pellagra, sprue after gastrectomy fish tapeworm infestation

Normocytic anemia, hemorrhage, hemolytic anemias, aplastic anemia.

Microcytic, hypochromic anemia, iron deficiency "Mediterranean anemia."

(+) Congenital hemolytic anemia.

(-) Hypochromic anemia, Mediterranean anemia, polycythemia vera.

(+) Acute general infections localized suppurative processes, severe chronic infection extensive neoplasm, myocardial infarction, late pregnancy

Thrombocytopenic purpura, hereditary hemorrhagic diathesis.

(+) Severe liver disease, vitamin K deficiency leukemias.

(+) Hemophilia.

(+) Scurvy scarlet fever measles, influenza, chronic renal disease, leukemia.

(+) Pernicious anemia, polycythemia, Hodgkin's disease

agranulocytosis.

 whole, use of, *Sept*, 1075
 Bone marrow cytology, *Sept*, 1324
 Bones, lesions, in hyperparathyroidism, *March*, 394, 396
 Brachial plexus injuries, *Jan*, 19
 Brain tumor in children, *July*, 892
 Brewers' yeast, dosages, *Sept*, 1303
 Bromides in convalescence, *Sept*, 1214
 in epilepsy, *Sept*, 1120
 Bromsahzol, *March*, 419
 Bromsulfalein test of liver function, *July*, 976
 Bronchial asthma, recent advances, *March*, 453
 Bronchiectasis, emergency aspects, *July*, 840
 surgical indications and treatment, *Sept*, 1284
 Broncholithiasis, emergency aspects, *July*, 842
 Bronchopneumonia in infants and children, *July*, 869
 penicillin in case report, *May*, 580
 Bronchus, adenoma of, hemoptysis in, *July*, 843
 Brucella, *March*, 359
 Brucellosis, *March*, 343
 penicillin failure in, *May*, 586
 Buboes, inguinal, in lymphogranuloma venereum, *May*, 668
 Bubonuli, *May*, 669, 670
 Burns, infection due to, penicillin in, *July*, 836
 shock in, sodium lactate in, *March*, 438
- CAFFEINE in epilepsy, *Sept*, 1122
 Calcium in dermatology, *Sept*, 1104
 Candida albicans, infections with, *March*, 323
 Carbon dioxide in bronchial asthma, *March*, 459
 Carbuncles, penicillin in, *July*, 836
 Carcinoma of colon, proximal portion, iron deficiency and anemia associated with, *July*, 958
 of lung, emergency aspects, *July*, 842
 primary surgical indications and treatment, *Sept*, 1282
 of prostate, estrogen therapy, *March*, 435
 of stomach, diagnosis, *March*, 489
 gastroscopy in, *March*, 499
 Caruncle of urethra, *July*, 1007

- Cataplexy, potassium chloride in, *March* 422
- Catarh, gastric, with peptic ulcer, *May* 628
- Catalgalia, *Jan.*, 13
- Cauterization of cervix in chronic cervicitis, *July* 1002
- Cavernostomy in tuberculous, *March* 430
- Cavernous sinus thrombosis, emergency treatment, *July* 824
- Cedilanid, *March* 424 529
- Cellulitis, penicillin in *May*, 85- *July* 836
- Cerebral palsies of children rehabilitation in, *May* 792 819
- thrombosis in children, *July* 894
- Cervicitis, chronic, *July*, 998
- Chaddock's sign in pyramidal tract lesions, *Jan.*, 50
- Chemotherapy in brucellosis, *March*, 357
- in lymphogranuloma venereum, *May* 682
- in tuberculosis *March* 445 *July* 918
- in urinary tract infections, *May*, 574, 575
- Children, cardiac emergencies in, *July* 871
- gastro-intestinal emergencies in, *July* 878
- neurologic emergencies in, *July* 886
- respiratory tract emergencies in, *July* 864
- urinary tract emergencies in, *July* 874
- Chloral hydrate in convalescence *Sept.*, 1214
- Cholera, postwar problem of *July* 901
- Cholesterothorax, *March* 507 510
- Choline in cirrhosis of liver *March* 429 484
- Chordotomy for intractable pain, *Jan.*, 98
- Choriomeningitis, lymphocytic, benign, *Jan.*, 36
- Chromoblastomycosis, *March* 336
- Chylothorax, *March* 506 510
- Cigarette smoking, effect on heart and peripheral blood vessels, *July* 949
- Circus movement, *Jan.*, 216
- Cirrhosis of liver correlation of composite liver function study with liver biopsy *March* 363
- diagnosis *March* 480
- dietary treatment, *March* 276, 429 484 485 *May* 655
- etiology, *March* 273 479
- hypotrophic substances in *March* 428 484, *May* 658
- nutritional deficiencies as basis *May* 655
- symptoms and signs, *March* 275
- treatment, recent advances, *March* 273 479
- Cirrhosis of liver with clinical features of xanthomatous biliary cirrhosis but with confirmation at biopsy *July* 1054
- Clawed hand in ulnar nerve injury *Jan.*, 15
- Clonus in pyramidal tract lesions, *Jan.*, 56
- Coccidioidin, *March* 334
- Coccidioidomycosis, *March* 332
- postwar problem of *July* 907
- Cold, common, propadrine hydrochloride in *March* 420
- Colic in infants *July* 8 8
- Colitis, chronic ulcerative, sulfathalidine in *March* 427
- Colon diverticulitis and diverticulosis clinical study *May* 639
- proximal portion, carcinoma of iron deficiency and anemia associated with *July* 958
- Coma, diabetic, *July* 893
- in children, emergency treatment *July* 892
- Communicable diseases, common, active immunization against, *Sept.*, 1238
- Complement fixation test in lymphogranuloma venereum *May* 678
- Convalescence bed rest in, undesirable effects, *May* 720 748, 809
- in home, rehabilitation problems, *May* 818
- in hospital, rehabilitation problems, *May* 808
- management of patient, *Sept.*, 1210
- Convalescent care of rheumatic fever in Army Air Forces, *May* 765
- hospital, Army Air Forces, role of *May* 721
- serum, *Aug.*, 1035
- training program, Army Air Forces, *May* 716

- Convulsions in children, emergency treatment, *July* 886
- Convulsive shock therapy in psychoses, *Sept.*, 1232
- Coronary thrombosis, *Sept.*, 1160
- electrocardiograms in, *May* 598
- pain of differential diagnosis, *March* 513
- quinidine in, *Jan.*, 22,
- restriction of activity in and extent of myocardial infarction, *March* 405
- Creams dermatologic, *Sept.*, 1100
- protective *Sept.*, 1103
- Criminal responsibility epilepsy and, *Jan.*, 212
- insanity and *Jan.*, 195
- mental retardation and, *Jan.*, 203
- Croup *July* 864

- Cryptococcosis, *March*, 335
 Curare, new uses, *March*, 423
 test for myasthenia gravis, *Jan*, 129
 Cushing's syndrome, *July*, 1011, *Sept*, 1224
 Cyst, suprasellar, obesity with, *Sept*, 1222
 Cystic disease of lung, emergency aspects, *July*, 845
 Cystine in liver disease, *March*, 429
 Cystitis, acute, in female, *Sept*, 1202
 chronic interstitial, *Sept*, 1205
- D-DESOXYEPHEDRINE hydrochloride, *March*, 420
 Deafness, conductive, relation to lymphoid hyperplasia of endometrium and x-ray therapy, *Sept*, 1251
 Deficiency diseases, arthralgia due to, *Sept*, 1271
 rehabilitation problems, *May*, 794
 Dementia praecox, *Jan*, 148
 Demerol, *March*, 417
 in convalescence, *Sept*, 1212
 Dengue fever, postwar problem of, *July*, 900
 Depression in combat crews, *May*, 732
 in returned soldiers, *May*, 736
 Dermatitis, acute, emergency aspects, *July*, 833
 Dermatology, nonsurgical emergencies encountered in, *July*, 833
 Dermatophytosis, *March*, 323
 treatment, *March*, 326
 Dermatoses, common, treatment, *Sept*, 1095
 Desoxycorticosterone acetate in Addison's disease, *March*, 435
 Diabetes insipidus, *July*, 1009
 mellitus, *July*, 1014
 globin insulin in, *March*, 436
 Diabetic coma, *July*, 893
 electrocardiogram in, *May*, 608
 Diarrhea, acute, in infants and children, *July*, 882
 Diasone in tuberculosis, *March*, 447, 448, *July*, 921
 Dichlorophenarsine hydrochloride in syphilis, *March*, 438
 Dicoumarol in prevention of embolism and thrombosis, *March*, 430, 431, *July*, 840, 929
 Dienoestrol, *March*, 435
 Diet in acidosis of chronic diffuse glomerulonephritis, *Sept*, 1196
 in cirrhosis of liver, *March*, 276, 427, 484, *May*, 655
 in convalescence, *Sept*, 1215
 in epilepsy, *Sept*, 1119
 in nephrosis, *Sept*, 1186
 in nutritional deficiencies, *May*, 799-802
 in obesity in children, *Sept*, 1227
- Diet in peptic ulcer, fundamental importance, in Army hospital, *May*, 706
 in pernicious anemia, *Jan*, 244
 in recurrent peptic ulcer, *Sept*, 1167
 in rehabilitation, *May*, 794
 Digilanid, *March*, 423
 Digitaline native, *March*, 423
 Digitalis, blood-clotting and, *March*, 431
 effects on electrocardiogram, *May*, 609
 in arrhythmias, *March*, 531
 in heart failure, *March*, 524
 preparations and uses, *March*, 423, 524
 Digitoxin, *March*, 423
 Digoxin, *March*, 424, 529
 Dihydrotachysterol in hyperparathyroidism, *March*, 402
 Dilantin sodium in bronchial asthma, *March*, 459
 Dilaudid in convalescence, *Sept*, 1212
 Diphtheria, immunization, *Sept*, 1240
 laryngeal, *July*, 866
 Diuresis in nephrosis, *Sept*, 1187
 Diuretics, new, *March*, 424
 Diverticulitis of colon, *May*, 639
 Diverticulosis of colon, clinical study, *May*, 639
 Diverticulum, urethral, *July*, 1008
 Drop wrist in radial nerve injury, *Jan*, 10
 Dye excretion tests of liver function, *July*, 976
 Dysentery, amebic, postwar problem of, *July*, 906
 bacillary, postwar problem of, *July*, 905
 sulfasuxidine in, *March*, 426
 sulfathalidine in, *March*, 426
 sulfonamides in, *Sept*, 1311
 Dysmenorrhea, hormone therapy, *Jan*, 259, 262, 265, 267
 Dyspnea, pulmonary disturbances causing, emergency aspects, *July*, 843
- ECLAMPSIA, *July*, 852
 Ectopic pregnancy, ruptured, *July*, 854, 856
 Edema of lung, acute, emergency aspects, *July*, 837
 Educational retraining in Army Air Forces, *May*, 721
 Electrocardiography, uses in medicine, *May*, 590
 ventricular gradient in, *March*, 464
 Electrodiagnosis in peripheral nerve injuries, *Jan*, 23
 Electroencephalography in epilepsy, *Sept*, 1118, 1126
 Electroshock therapy in psychoses, *Sept*, 1232
 with insomnia, *Jan*, 192
 outpatient, in psychiatric disorders, *Jan*, 165

- Embolism prevention, dicoumarol in *March* 430, 431, *July* 840 929
 heparin in *March*, 431 *July* 933
 pulmonary, emergency aspects *July* 839
 prevention exercises for, *May* 789
 Emergencies, medical, symposium on *July* 833
 Emotional states, arthralgia due to *Sept* 1271
 Emotions, neuropsychology of, *May* 744
 Empyema, pyogenic *March*, 507, 510
 Emulsions, *Sept.*, 1099
 Encephalitis, acute, emergency treatment *July*, 895
 Encephalo myelo-radikuloneuritis, acute, *Jan.*, 1
 Endocarditis, bacterial, subacute non hemolytic streptococcus, treatment with penicillin *Sept.*, 1229
 penicillin in *May*, 583
 brucella, *March* 348
 subacute bacterial, therapeutics, *March* 425
 Endocrine glands real versus supposed disturbances, *July*, 1009
 system, therapeutics *March*, 433
 therapy in dermatology *Sept.*, 1111
 in menstrual disorders, *Jan.*, 251
 Endometrial biopsy *Jan* 252
 Enuresis, ephedrine in *March*, 420
 Ephedrine in asthma in children *July* 867
 in enuresis, *March* 420
 in myasthenia gravis, *Jan.*, 134 *March* 421
 Epidermatophytosis, *March* 323
 Epilepsy, criminal responsibility and *Jan.*, 212
 diagnosis, *Sept* 1114
 electrocardiogram in *May* 608
 electroencephalography in *Sept.*, 1118 1126
 glutamic acid in *March* 418
 treatment, *Sept.*, 1114 1119
 types of seizures, *Sept.*, 1115
 Epinephrine in asthma in children *July*, 867
 Erb's paralysis in brachial plexus injuries, *Jan.*, 19
 Erysipelas, penicillin in *July* 836
 Erysipeloid penicillin in *July* 836
 Erythrocytes resuspended uses of *March* 432 *Sept.*, 1077
 sedimentation rate, clinical significance, *July* 937
 Esthlovene, *May* 670
 Estrogen therapy in menstrual disorders *Jan.*, 239
 in prostatic cancer *March* 435
 new products, *March* 435
 Ether in oil intramuscularly, in bronchial asthma, *March* 459
 Ethinyl estradiol *March*, 435
 Exercises in pulmonary embolism prevention *May*, 789
 therapeutic in convalescence *May* 787 810
 Exhaustion states in Army and in industry *May* 771
 Expectorants in bronchial asthma, *March*, 458
 Extrasystoles, quinidine in *Jan.*, 227
 Eye signs in brucellosis, *March* 347
 FACIAL pain, neoplasia as cause *Jan* 91
 relief of *Jan.*, 73
 symptomatic, *Jan.*, 87
 Fasciculation neostigmine in *March* 422
 Fatigue, arthralgia due to *Sept.*, 1271
 "operational" *May* 729
 states in Army and in industry, *May* 771
 Fats, plasma, in liver disease, *July*, 979
 Fear electrocardiographic changes induced by *May*, 618
 Feeble-mindedness, criminal responsibility and, *Jan* 208
 Feet dermatophytosis of, *March*, 323
 Femoral nerve injuries, *Jan.*, 23
 Ferrous carbonate in facial pain, *Jan.*, 77
 Fever therapy in brucellosis, *March*, 360
 Febrin foam and film *Sept* 1087
 in neurosurgery *March* 432
 Fibrositis, etiology environmental factors, *May* 568
 Filariasis postwar problem of *July*, 903
 Fluids administration, in chronic diffuse glomerulonephritis, *Sept.*, 1193
 in diarrheas of infancy, *July* 882
 Fluorescence test for dermatophytosis, *March* 325
 Focal fit *Sept.*, 1115 1122
 Fractures in hyperparathyroidism *March* 394
 Frei test *May* 677
 inverted *May*, 678
 Friedrich's disease, electrocardiogram in *May* 607
 Fröblich's syndrome *Sept.*, 1222
 Functional tests, electrocardiogram in *May* 615
 Fungus infections, pleural effusions of, *March* 508 511
 sodium propionate in *March* 438
 Furmethide in bladder atony *March* 421
 Furunculosis penicillin in *July* 836
 GALACTOSE tolerance test of liver function *July* 977
 Gallbladder disease electrocardiograms in, *May* 606
 Gastric analysis diagnostic value *March* 492

- Gastritis, diagnosis, *March*, 489
gastroscopy in, *March*, 498
Gastroduodenal disease, diagnosis, *March*, 489
Gastrointestinal tract, acute nonsurgical emergencies related to, *July*, 878
therapeutics, *March*, 426
Gastroscopy, *March*, 497
Gelatin as blood substitute, *March*, 433, *Sept*, 1091
Globin insulin in diabetes, *March*, 436
Globulin, serum, immune, *Sept*, 1087
Glomerulonephritis, acute, in children, electrocardiogram in, *May*, 606
penicillin in, *May*, 582
chronic diffuse, management, *Sept*, 1184
differential diagnosis, *July*, 990
Glomerulosclerosis, intercapillary, *March*, 538
Glucosides, cardiac, *March*, 423, 529
Glutamic acid in epilepsy, *March*, 418, *Sept*, 1122
Glycine in myasthenia gravis, *Jan*, 135
Gold salts therapy in arthritis, *Sept*, 1278
Gonadotropin therapy in menstrual disorders, *Jan*, 256
Gonda sign in pyramidal tract lesions, *Jan*, 57
Gonorrhea, penicillin-resistant, *May*, 688
sulfonamides in, *Sept*, 1311
Gordon's sign in pyramidal tract lesions, *Jan*, 53
Gout, etiology, environmental factors, *May*, 567
Grafts nerve, *Jan*, 27
Gramicidin in dermatology, *Sept*, 1107
Grand mal, *Sept*, 1116, 1122
Groin, dermatophytosis of, *March*, 323
Guanidine in myasthenia gravis, *Jan*, 134
Guillain-Barré syndrome, *Jan*, 1
- HEAD injuries in children, coma due to, *July*, 893
emergency treatment, *July*, 891
Headache, tension, *May*, 568
Heart disease, asthma with, in children, *July*, 871
electrocardiograms in, *May*, 595
pain of, differential diagnosis, *March*, 513
quinidine in, *Jan*, 215
effect of cigarette smoking on, *July*, 949
emergencies, *Sept*, 1154
in pediatric practice, *July*, 871
failure, acute, in children, *July*, 872
left-sided, *Sept*, 1159
congestive, with hypertension, *March*, 542
digitalis in, *March*, 524
irregularities, electrocardiograms in, *May*, 590
- Heart lesions in hyperparathyroidism, *March*, 395
position, electrocardiogram and, *May*, 608
structural abnormalities, electrocardiograms in, *May*, 595
tamponade, *Sept*, 1158
therapeutics, *March*, 423
Heat therapy in rehabilitation, *May*, 787
Hematoma, subdural, *Jan*, 62
chronic, diagnosis, importance of, *July*, 1042
Hemolytic anemia, acute acquired, *May*, 695
Hemophilia, plasma in, *Sept*, 1085
Hemoptysis, *July*, 837
Hemorrhage in liver damage, control of, *March*, 432
intracranial, convulsions of, *July*, 888
of early pregnancy, *July*, 853
of late pregnancy, *July*, 855

PHILADELPHIA NUMBER

SYMPOSIUM ON RECENT ADVANCES IN GYNECOLOGY AND OBSTETRICS

FOREWORD

THE work presented in this volume comprises clinical investigation and reports by members of the staffs of Philadelphia hospitals, principally the Philadelphia Lying-in Hospital and the Jefferson Medical College Hospital. The object of this Symposium is to fulfill the need of bringing the recent advances in obstetrics and gynecology to the men in the service as well as to those returned to practice, so that they may have an up-to-date report of the developments which have occurred during the war years. Emphasis has been placed upon the newer methods of therapy as compared with the older methods and the establishment of improved practices in the treatment of gynecologic and obstetric complications.

It is to be understood that some of these practices are still in the experimental stage but since clinical trial has shown that they are worthy of continued use and investigation, they deserve mention in this volume.

This compilation cannot be expected to fulfill the requirements of a complete refresher course in this specialty, but it does point out the improvements and changes that have taken place while the obstetrician-gynecologist was serving his country in other capacities.

Some of the articles have been contributed voluntarily by members of the Philadelphia medical profession and the selection of these contributions has been made with the thorough understanding that the authors are in a position to have established the value of the procedures from clinical experience.

It is hoped that these presentations will not only stimulate additional work and reviews of the specialty but that the profession at large will take advantage of the authors' and publisher's efforts and acquaint themselves with every detail contained therein.

It is with distinct satisfaction that I present this Symposium on the recent advances in obstetrics and gynecology

NORRIS W VAUX, M.D

GYNECOLOGIC EXAMINATION—PREMARITAL COUNSEL

ROBERT C McELROY, MD

AN introduction to gynecic treatises and study must, of necessity, be concerned with examination of the patient. It is assumed that adequate basic training in the fundamental embryology, anatomy, histology and pathology as related to this field has been acquired

Gynecologic examination is as integral a part of the armamentarium of the general practitioner as it is to the specialist. The great differences in the approach of the two types of practitioner lie in the allotment of the facts in the history taking, time and facility for examination, systematic approach and thoroughness. Errors in diagnosis are due to the sins of omission rather than commission.

Preliminary preparation of the patient for examination requires that the bladder be emptied immediately prior to examination. The rectum should be emptied and enemas utilized when necessary. All constrictive clothing and supportive garments should be removed. Confidence and cooperation of the patient will facilitate matters to the utmost. Gentleness and tact combined with reassurance will mentally prepare the patient for an examination that notoriously carries a stigma of pain and embarrassment. The presence of a nurse, assistant or some third disinterested party serves as protection to the physician but offers little benefit to the patient beyond moral support.

HISTORY

History taking is a necessary preface to any physical examination. Facts common to all medical history of either specialized or general nature must be noted to cover general and systemic etiologic factors of pelvic disease. Certain facts pertinent to the female in respect to her age, color and marital state (past and present) must be noted. An accurate menstrual history covering age of onset, type of flow, whether regular or irregular, interval, duration and quantity of flow (number of napkins), the character, whether accompanied by clots or passage of tissue, color, odor, association of pain, its location, radiation and character, time in relation to flow, the date of the last menstruation, both normal and abnormal, and finally menopausal symptoms, if the latter be present, must be recorded. Childbearing being responsible for or related to complaints, demands that an accurate obstetrical history include the number of labors and abortions, their respective dates, character and the method of termination, the duration of the puerperia

* Instructor, Department of Obstetrics and Gynecology, School of Medicine, University of Pennsylvania, Assistant Obstetrician and Gynecologist, Philadelphia Lying-in, University of Pennsylvania and Philadelphia General Hospitals

and their final results, the size of the infant and its condition at birth, the number of living or dead children with the cause for the deaths recorded. The presence of leukorrhea with notation of its character, color, odor and production of pruritus will aid in tracing the etiology of this subjective finding.

Menstrual disturbances may be an indicator of either pelvic or systemic disease such as tuberculosis, severe anemia, blood dyscrasia or endocrine abnormality not necessarily pelvic. The origin of the bleeding must be determined since urinary and rectal origins may be confused with genital sites.

Pain as a gynecologic symptom may be in the form of backache, cramps, tenesmus, headache, dyspareunia, urinary or rectal. What is its reference in the pelvis? It should be recalled that contralateral pain is common in pelvic disease and that reference to distant unrelated areas such as the Curtis-Fitzhugh syndrome may deviate the investigation to another field. Right shoulder pain in ectopic pregnancy, ruptured cyst and post-tubal insufflation all have pelvic origins. Ovarian pain and testicular pain are similar in the production of vertigo and nausea. Tubal pain is sharp and stabbing and associated with abnormal tenderness. Uterine pain may be colicky, constant or pressural in manifestation. Vaginal pain may be associated with burning, tingling and itching.

Leukorrheal discharges must be investigated as to origin and causative organisms. For this purpose facilities for stained or wet smears should be at hand. An abnormal leukorrhea should always be regarded with suspicion because it may be the first symptom of malignant disease.

The contiguous urinary tract makes any deviation from the normal act of micturition an accompanying symptom of pelvic disease. Urinary disease such as ureteral dysmenorrhea confuses the examiner and urologic training or aid should be sought. Diurnal frequency, nocturia, urgency, burning, pain, hematuria, incontinence, dribbling and retention are the classic subjective phenomena. Objective findings should take note of the color, turbidity and odor of the urine. Urinary disease may be the prime etiologic factor in association with symptoms found in mild gynecic disease. An outstanding example of this is the trigonitis with small cystocele.

Lower intestinal tract phenomena may be caused by gynecologic disease, and vice versa. The bowel habit, whether featured by constipation or diarrhea, may have an important bearing on the patient's symptoms. Mucous diarrhea is almost diagnostic of pelvic abscess, whether tubal or appendiceal in origin.

The previous medical history should include a notation of surgical procedures and their resultant effects on gynecologic complaints with emphasis on the effect on menses or fertility. In regard to the latter the husband's previous medical history or occupation may contribute information that is valuable.

GYNECOLOGIC EXAMINATION

Equipment—The instruments for gynecologic examination are not numerous but they must be specially adapted to suit the needs of the field. The examining table should be one of adjustable length with the facility to elevate the head and shoulders. The supports for the extremities may utilize either heel rests or leg holders. The covering mattress should be firm, smooth yet comfortable. Drawer space at the foot should contain the equipment to be mentioned below.

Lighting facility should be either a no-spot lamp, head mirror or light, or a speculum light. The ordinary goose-neck is awkward and burns the patient and the operator while obstructing the view.

The remainder of the equipment includes rubber gloves, lubricant, various types and sizes of specula, tenacula, dressing forceps, steel or glass catheter, suction curette, dilators, sounds, probes, biopsy forceps, cautery or electro coagulation apparatus, pressometer or Rubin apparatus, microscope, needles and syringes, sterilizer, diaphragm rings, solutions, blood counting apparatus and pessaries.

Position of the Patient—The gynecology examination necessitates a variance in position of the patient to secure completeness and accuracy. The recumbent, dorsal lithotomy, Sims', knee-chest and Trendelenburg positions all have peculiar usefulness. Abdominal examination is best in the recumbent, bimanual examination by the dorsal lithotomy, Sims' and knee-chest for fistulas or uterine replacement.

The Examination—Proper positioning with adequate coverage to prevent undue exposure is the correct approach to examination. *Abdominal examination* precedes pelvic examination. Tumor masses, tympanites, ascites, rigidity and tenderness as well as peristaltic activity are noted. Tumor masses may be smooth or irregular, firm or elastic and do not produce distention of the flanks. Ascites show a fluid wave, shifting dullness and dullness in the flanks. Tympanites causes uniform distention with the characteristic high-pitched note on percussion. The presence of fetal parts and heart sounds makes pregnancy an easier diagnosis. Rigidity of the abdomen or absence of peristalsis indicates some inflammatory lesion and may be secondary to a pelvic lesion or a complication of it. Tumor masses caused by the urinary bladder may be dispelled by the catheter. Coronal tympany is present in ovarian cysts.

On completion of the abdominal examination the *pelvic examination* is next in order. It is carried out with the gloved hand to protect the operator and to respect the aesthetic sense of the patient. One or both hands may be used depending on the ability to completely explore the pelvis. The patient is cautioned that the examination is discomforting but not painful and she may expedite matters by relaxation and deep breathing.

Fundamentally, the exploration can be accomplished thoroughly by means of the internal and external hands to exert counterpressure. The

size, shape, consistency, motility and tenderness of the organs are determined. An accurate knowledge of the normals is essential, and is gained only by wide experience.

The procedure is begun by inspection and palpation of the external genitalia. Congenital abnormalities, hypertrophy, cutaneous lesions, hair distribution, discharge or swelling are noted. Skin lesions that affect other portions of the body may affect this area. Hair distribution may give a clue to endocrine disease. Swellings may be due to inflammation, tumors, varicose veins or hematomas. Bartholin's glands may be palpated in the bases of the labia majora with their orifices in the labia minora. Vaginal penetration is initiated with one finger, the index, and followed by the middle finger. The patient is asked to strain demonstrating relaxation or the presence of urethrocele, cystocele or rectocele. The urinary meatus is inspected for caruncles, mucosal prolapse or cysts. Milking the urethra produces abnormal discharges from Skene's tubules.

Deep vaginal penetration is completed by pressing against the rectum and perineal body, steadying the elbow against the body or hip to allow free motion of the fingers. Care is exercised not to titillate the clitoris or urethra. The vaginal size, shape, consistency, volume, sensitiveness and local heat are noted as well as masses encroaching on it. The latter include Gartner duct cysts, vaginal inclusion cysts, extra-vaginal tumors and inflammatory lesions. Congenital malformations or fistulas when present should be noted.

The cervix projects into the vaginal vault normally at a right angle causing it to point downward and backward. Deviations of this give valuable clues to the position of the uterus. Retroversion forces the cervix towards the symphysis, upward and forward as does pelvic abscesses, cysts or fibromyomas. Lateral deviations indicate that the uterus is either pushed over by a tumor or pulled over by adhesions. Cervical erosions, ectropions, lacerations, cysts, tumors, hypertrophy and elongation as well as the state of the os may be determined. Descensus must be differentiated from elongation with the sound or vulsellum traction. Vaginal hemorrhage may originate from the cervix or uterine cavity and this can be easily observed.

Above the cervix is the uterine body, which is usually in slight anteversion and ante flexion. It is felt by placing the vaginal fingers anterior to the cervix and attempting to cause the abdominal and vaginal fingers to meet over the symphysis pubis. Absence of the body here indicates some retrodisplacement. The cul-de-sac of Douglas is then explored for the smooth, rounded fundal mass and it is differentiated from abscesses, tumors or hematoceles. Absence of the body in either location indicates midposition or lateral deviation. When the fundus is located, the size, shape, consistency, motility and sensitiveness of the uterus is determined. Retrodisplacements are judged as to adherence and replaceability. Lateral deviation is differentiated from tumors and ad-

hesions The uterine mass is differentiated from other pelvic masses by demarcation or sounding

The uterine ligaments are not easily felt, but the round ligaments may be palpated as a cordlike mass arising from the cornua The uterosacral ligaments are felt in the cul-de-sac and are best noted in pelvic endometriosis or spreading carcinoma

Examination of the adnexa requires skill and experience They are motile for great distances in almost any direction and tend to slide away from the exploring hands The normal tube cannot be palpated but enlargements due to ectopic pregnancy, salpingitis, pyosalpinx or hydrosalpinx can be felt. An ectopic gestation is exquisitely tender while the other conditions show variations in shape and a lesser degree of tenderness The ovary can be palpated, but must be trapped between the abdominal or vaginal hands as well as the lateral pelvic wall It must, therefore, be scooped into this site The ovary has a sensitivity similar to that of the testicle and pressure upon it may produce nausea or vertigo. Cysts have the characteristic elastic feel, except the dermoid, which is stony hard and located anterior to the broad ligament They are freely motile usually, while the parovarian cyst is in close approximation to the uterus and is fixed Free motility may cause confusion with a pedunculated fibroid The small cysts are retention in type while the large ones are proliferative

Completeness demands that the bladder and ureters be palpated for masses or tenderness During the palpation of the latter the uterine arteries may be felt in the lateral fornices

It is truly said the gynecologists make no rectal examinations and the surgeon fails to utilize the vagina The rectum affords an additional portal of entry especially in the virgin or to determine the state of the rectovaginal septum in abscess or endometriosis Rectal tenderness is prominent in appendicitis

Instrumentation gives further conclusive evidence by exposure of the vagina and cervix with the speculum Uterine replacement may be accomplished by traction on the cervix with the vulsellum The uterine sound shows the direction and depth of the endometrial cavity and if bleeding is encountered is helpful in the Clark test for fundal carcinoma Intracavity tumors may be felt by this method Before sounding the uterus the date of the last menstruation must be known in order not to produce an abortion, frequently the reason a patient consults the physician The fine probe will locate fistulas or sinus tracts The biopsy forceps should be wisely employed to determine the histopathology of suspicious lesions Insensitiveness of the cervix to manipulation except dilatation affords opportunity for the painless application of cauterization and coagulation procedures to erosions and ectropions Marked superficial vascularity, however, contraindicates cauterization because of the possibility of additional uncontrollable bleeding Intrapelvic infection may be activated by such a procedure

Tubal insufflation may be easily accomplished for sterility study. Endometrial biopsy for malignancy or sterility study may be similarly performed. Postcoital ejaculation specimens of semen may be studied for male fertility. The vaginal smear affords valuable evidence in the hands of the expert for the study of malignancy or hormonal control as well as the treatment of vulvovaginitis in the child. The Hinselmann colposcope may be used by the expert for the study of malignant lesions. The Schuller test of painting the cervix with iodine solution outlines the site for biopsy purposes. The microscopic examination of leukorrheal discharges aids in differentiating trichomonas or moniliasis. The catheterized urinalysis affords more accurate diagnosis of urinary findings, and results in urine which is more suitable for either the Friedman or Aschheim-Zondek tests for pregnancy. The former is now more accurately done as a serum prolactin determination on a qualitative basis of the blood. Further diagnostic aids are found in the dark-field examination of ulcerative lesions for primary lues or in culture for Ducrey bacillus in chancroid. Granulomatous lesions are differentiated by the Frei test for lymphogranuloma venereum or the smear for the Donovan bodies of granuloma inguinale.

On a therapeutic basis the vagina is utilized for douching, Elliott therapy or controlled douching, hormonal substitution by suppository or the intravaginal application of cone radiation therapy for malignancy, as well as the colpostat in radium application or as a site for the insertion of radium needles or radon seeds for cases of intractable hemorrhage in carcinoma that will not respond to other methods.

PREMARITAL COUNSEL

Premarital laws of various states require that medical examination of the prospective bride and bridegroom be made to rule out syphilitic and gonorrheal infection prior to marriage. These laws, forcing such examination, afford the physician the opportunity to offer these individuals advice in their new venture, which will serve to prepare them for a happy conjugal life and may prevent future marital unhappiness ending in divorce. Such advice may or may not be requested. It is sufficient to state that it is needed in practically all cases but may be received with antagonism unless the cases are individualized.

The time for the consultation cannot be accurately stated. Parents may provide utopia by their intelligent, early instruction to children when the first questions arise. The child should be led into open, frank discussion by stages until complete knowledge is acquired. Physical fitness is a "must" in all things except the vital functions of marriage and parenthood. Until recently there has been complete neglect of this and even now too much misinformation exists. If possible, instruction should begin before love, engagement and the premarital examination in order to allow sufficient time to emphasize and properly digest all

the considerations The entire field could only be covered thoroughly by successive consultation with the physician, psychiatrist and marriage counselor

Consultation with the physician is on an intimate and personal relationship which must be handled with the greatest tact and gentleness A short but pertinent history of previous illness should be combined with the examination, which should be general as well as pelvic The physician should bring to light certain definite attitudes, entrenched shames, inhibitions, ignorances and erogenous practices in order to disperse these and possibly aid the groom in his approach and ability to stimulate his bride Anatomic abnormalities should be noted and, if a tight hymen is present, it should be dilated or stretched with or without the aid of anesthesia and with full consent of both bride and groom This may be accomplished in several ways Instruction in douching will serve to dilate the orifice and accustom the vagina to a foreign body The patient may do the dilation by using her finger or thumb at repeated intervals to enlarge the opening The physician can accomplish it by slow, forceful dilation without anesthesia and tearing of the hymen If necessary anesthesia is employed When dilation is done, the woman can be assured that her first coitus will not be painful or unpleasant

In the case of the woman who has had unpleasant experiences or who masturbates, assurance can be given that these practices have not harmed her Such erogenous practices may give an index of stimulation points valuable in reaching a climax later on and the knowledge is passed on to the male as advice without revealing its source Variant positions should be known and described for satisfactory intercourse She should be instructed to accept and cooperate with her husband's caresses and to guide him where necessary The marital act is not a duty or chore simply to be tolerated because marriage vows have been spoken It is indulged in for expression of love and affection and the pleasure derived therefrom Simultaneous climax can be reached if sufficient practice is had and the proper areas stimulated Actual insertion of the phallus should not occur until the female climax is near in cases of premature ejaculation If this is very premature, urologic advice is recommended Coitus during the menses is not harmful and may be more satisfactory because of the increase in the sex response at that time A small douche will remove the messy character of the act A complete knowledge of contraceptive control is fundamental and the method best suited to the couple advised The diaphragm is most efficient and where this cannot be fitted, the condom is used until the hymen is dilated to permit the use of a diaphragm In cases of religious scruples the Ogino-Knaus method of rhythm control is advised Pregnancy should not be delayed too long since it will complete the final union of the family and serve to cement the marriage

The prospective groom requires advice particularly since most men have had previous sex experience but on a different basis. Before marriage the act was mainly for carnal satisfaction and usually with an experienced partner. Since the male orgasm is always easily reached, he may fail to consider his wife's reaction and failure of response. First of all he, too, must have a short history and physical examination to rule out disease or abnormalities. His ideas, fears, previous acts and erogenous practices should be brought to light and properly discussed. He must be instructed in his rights and duties to his bride as well as her rights and duties in the marital acts. He knows what his responses and stimulation points are and must be cautioned that they vary greatly with those of his wife. Her response is slower and less complete unless he is a clever lover and willing to cooperate with her and practice until the climax is simultaneous. He must be informed of her stimulation points and the necessity of precoital play until she is near the climax. This is accomplished by the proper mental approach combined with physical stimulation, culminating in complete and satisfactory intercourse. The approach should never be one which ever hints of the vulgar or profane but should be associated with expressions of affection and regard. He should protect his wife from intrusion and never indulge in the act when either partner is fatigued or unreceptive.

Both partners are to be informed that lack of orgasm is not lack of affection and as such does not demand rushing into the use of hormone injections or psychoanalysis. As Dickinson so aptly puts it, "we must combine goodness with the gonads and the new harmonies with hormones." The problem is not an insoluble one and with proper investigation and education the solution can be found. In respect to sex practices don't recommend and don't condemn. In regard to premarital practice don't answer affirmatively or negatively but point out the risks. The individuals should not necessarily know of each others experience because some individuals are unable to tolerate such knowledge.

Physical exercise will stimulate the sex urge and response. Since many women lead a sedentary life this activity should be advised. Men, on the other hand, indulge in exercise for the sheer enjoyment of it. Women fail to do so because it causes excess perspiration and contributes to ruffling of the general appearance. Exercise to the point of fatigue will be harmful and care is exercised not to reach this state.

Finally, the question arises as to who shall be educated in these facts. All groups are in need of such instruction. The colleges and universities are attempting to recognize the urgent need for it and are incorporating such courses in the curriculum. However, many times students are not honestly enrolled in the courses to secure knowledge, but because of the lure of the spicy subjects under discussion. It has been my personal observation that the highly intelligent have a much more

difficult time than others in harmonizing their sexual relations because they are afraid to admit ignorance of the subject and will go to the end to solve the problem themselves before seeking advice. They have more consideration for each other and when a problem arises they will make an attempt at a solution. If this fails they will practice continence or indulge only to satisfy their partner. The lower income groups rarely have these difficulties and certainly they infrequently seek advice. With the existing means of recreation they are able to secure sufficient exercise and are not leading a pace that is killing. They do not, as a rule, take into consideration the financial burden of pregnancy and rarely deny themselves because of an inability to provide a college education for the offspring. It is not intended to imply that they have less consideration for each other but that they more frequently enter into the act for sheer expression and pleasure. They have their problems, nevertheless, and premarital advice should always be available to them and should be offered without being rude.

The physician must preserve dignity and abstain from levity during all of the discussion. He must maintain a sympathetic and helpful attitude. He will remember that through education we can teach success in marriage and parenthood by enlisting effort, courage and intelligence, thus preventing the disastrous terminations of so many marriages in the divorce court. He can promote a new outlook on a problem that deserves more careful consideration than has been given it.

ADVANCES IN THE TREATMENT OF VAGINITIS

A E RAKOFF, MD *

PROGRESS in the treatment of vaginal infections and associated disorders of the vagina during the past several years has resulted from a better understanding of the biology and physiology of the vagina in health and disease as well as from the introduction of new chemotherapeutic drugs, antibiotics and hormonal preparations. Also of importance has been the improvement in the technics of applying medications to the vagina particularly with regard to the development of medications which could be effectively distributed over the entire lower genital tract and of the proper physical and chemical character to mix intimately with the vaginal and cervical secretions¹

BIOLOGY OF THE NORMAL VAGINA

The effective treatment of infections and discharges of the vagina requires an appreciation of the mechanism by which the normal biologic characteristics of the vagina are maintained²

The vaginal mucosa is under the direct influence of the ovarian hormones. The estrogens are the dominant factor in stimulating proliferation of the vaginal epithelium and thus maintaining a vaginal mucosa of normal thickness. The estrogens are also responsible for the deposition of glycogen in high concentration in the vaginal epithelium, progesterone may aid in this process, while androgens inhibit both proliferation and glycogen deposition. By the combined action of enzymes and bacteria the glycogen of the vaginal epithelium is metabolized and broken down to lactic acid. The resulting acidity of the vagina favors the growth of certain acidophilic bacteria, particularly the lactobacilli of Döderlein. These organisms tend to further increase the acidity of the vagina by utilizing glycogen and the carbohydrates resulting from the enzymatic breakdown of glycogen. The resulting pH of the vaginal secretion thus tends to become stabilized at 4.0 to 5.0 in the normal adult during the period of active ovarian function. Since very few other organisms can thrive in so acid an environment, Döderlein's bacilli quite commonly become established in practically pure culture in the normal vaginal tract. By this mechanism the genital tract is protected from exogenous infection.

In phases of diminished ovarian function such as in childhood, in the immediate postpartum period and in the postmenopausal years the diminished elaboration of estrogenic hormones produces a vaginal mucosa that is of diminished thickness, with little or no glycogen content and a less acid or even alkaline secretion ranging from pH 5.0 to 8.0. Under these latter circumstances Döderlein's bacilli tend to disappear from the vaginal secretion. The presence or absence of the lactobacilli is thus largely dependent upon the vaginal acidity. Almost all patients with a vaginal flora of Döderlein's bacilli alone (so called Grade I vaginal flora) have a vaginal pH ranging from 3.9 to 5.0. The majority of patients with a

From the Departments of Obstetrics and Gynecology, Jefferson Medical College and Hospital, Philadelphia

* Assistant Demonstrator in Obstetrics, Instructor in Gynecology, Jefferson Medical College. Director of the Endocrine Laboratories, Jefferson Hospital

Grade II flora (Döderlein's bacilli plus other organisms) have a vaginal pH ranging from 4.6 to 5.5. In the Grade III type (a mixed flora in which there are no Döderlein's bacilli) the pH generally ranges from 5.1 to 6.0 and even higher in the presence of certain infections.

It is thus quite apparent that, in addition to demonstrating the presence or absence of some specific infecting organism, it is of equal importance to study the vaginal secretion for its cytologic content—as an index of estrogenic function, glycogen content, pH and type of bacterial flora in order adequately to evaluate and treat various types of vaginal infections and discharges.

"NONSPECIFIC INFECTIONS

Low grade nonspecific infections of the vagina are very commonly encountered. They may occur whenever there has been interference with the mechanism for maintaining the normal physiology of the vagina. In *ovarian dysfunctions* associated with estrogen deficiencies, glycogen concentration becomes diminished, the vaginal acidity is reduced and Döderlein's bacilli are replaced by a variety of organisms. The result is an alteration in the character of the vaginal secretion and not infrequently a low grade diffuse vaginitis. The pH of the vaginal secretion can also be altered by the persistent use of *alkaline* or *irritating chemical douches* thus resulting in the displacement of Döderlein's bacilli by less favorable organisms, but once the latter have established themselves and have created an inflammatory reaction of the vaginal mucosa, this abnormal mechanism may continue despite normal ovarian function. *Mechanical trauma* such as may occur from the long continued use of pessaries can also produce an inflammatory reaction. *Cervical infections* also quite commonly produce a nonspecific vaginitis by constantly decreasing the vaginal acidity with copious amounts of alkaline cervical discharge.

The treatment of these nonspecific infections obviously necessitates the correction of the underlying etiologic factor. If there is an associated ovarian deficiency, this should be corrected by appropriate endocrine therapy. If the cervix is infected, cauterization or conization should be employed where necessary. The use of all irritating douches, the application of irritating chemicals and mechanical trauma should be discontinued. Finally, measures to favor the return of the normal vaginal flora should be instituted. This can be most readily accomplished by creating an acid vaginal media. The use of acid vaginal douches several times daily is quite commonly recommended. For this purpose one may employ simple vinegar, 1 tablespoonful to 2 quarts of water; a saturated solution of boric acid, or lactic acid.² A suitable prescription is as follows:

	Gm. or Cc.
℞ Chlorthymol	13
Menthol	2.0
Methyl salicylate	2.0
Lactic in sufficient quantity	to make 180.0

Mix and label. A teaspoon in 2 quarts of hot water to be used as a vaginal douche morning and evening.

Much more satisfactory than the acid douche is the use of a water-dispersable acid vaginal jelly* which can be introduced into the vagina once or twice daily and which remains in contact with the vaginal mucosa over a prolonged period of time and thus more effectively creates a suitable acid medium.^{4, 5, 6} A very satisfactory preparation* consists of acetic acid, oxyquinoline sulfate, ricinoleic acid, boric acid and glycerine in a suitable vehicle. This jelly may be introduced at bedtime by the use of a special vaginal applicator containing 5 cc, which is followed in the morning by a simple acid douche. Persistent use of the vaginal jelly for several weeks generally leads to restoration of the normal vaginal flora which tends to persist provided any other underlying factors have been corrected.

ATROPHIC VAGINITIS

In the presence of a marked ovarian deficiency the vaginal mucosa may atrophy to a thin tissue-paperlike structure consisting of only a few layers of cells. Because of the susceptibility of this thin tissue to trauma and because of the associated decrease in vaginal acidity, inflammation, ulceration and infection readily result.

This type of condition can be readily corrected by administering estrogenic hormones in sufficient amount to cause proliferation of the vaginal epithelium and by treating the associated nonspecific infection by the methods already prescribed. A much more specific and rapid cure can be effected by applying the estrogenic hormone locally to the vaginal mucosa. This can be accomplished by the use of vaginal suppositories containing natural and synthetic estrogens or even better we have found the use of a water-dispersable acid jelly containing stilbestrol† in concentration of 0.5 mg per cc. Five cubic centimeters of this jelly can be introduced nightly into the vagina by means of a special applicator and followed the next morning with a simple acid douche. By applying the hormone to the vagina locally intense cornification can be rapidly induced without producing excessive systemic effects of hyperestrogenism. After initial cure has been obtained the jelly may be used once or twice weekly as required to maintain a healthy vaginal mucosa.

POSTPARTUM VAGINITIS

A nonspecific vaginitis frequently occurs in the postpartum period because of trauma from delivery, the bathing of the vaginal mucosa with the alkaline secretions from the uterus and cervix, and because the vaginal mucosa has become thin and glycogen-poor in this phase of diminished ovarian function. This type of infection responds quickly to an acid vaginal jelly and acid douches. Even more satisfactory is the

* Aci-Jel supplied by Ortho Pharmaceutical Corp., Linden, New Jersey

† Generously supplied to us for investigational use as "Gynecological Cream" by Ortho Pharmaceutical Corp., Linden, New Jersey

response which can be obtained with local use of an acid jelly containing stilbestrol as described above.

A procedure which we have found very satisfactory in our post-natal clinic is to have patients with excessive discharge or frank vaginitis use an acid jelly and an acid douche from the fourth to the eighth weeks postpartum. At that time any cauterization of the cervix which is necessary can be carried out. If vaginitis persists after the cervix has healed, the use of the stilbestrol jelly will generally effect a rapid cure. When used locally in this fashion it generally does not interfere with lactation.

HYPERHORMONAL LEUKORRHEA

An excessive amount of normal vaginal secretion is sometimes encountered, particularly in adolescent girls and young unmarried women. This type of discharge is due to excessive stimulation of the lower genital tract by estrogens, resulting either from a state of hyperestrogenism or marked responsiveness of the vagina and cervix to normal estrogen concentrations. This type of discharge quite normally occurs during pregnancy.

The treatment of this type of leukorrhea is very unsatisfactory. Much can be accomplished by assuring the patient that the discharge is of normal character and not due to infection. A simple saline douche twice daily helps to keep the patient more comfortable. In very troublesome cases methyl testosterone, 5 mg daily, can be given by mouth, this often diminishes the estrogen effect and in this dosage rarely gives rise to untoward androgenic symptoms.

TRICHOMONAS VAGINITIS

Trichomonas infestation of the vagina remains one of the most troublesome problems in gynecology. Despite the fact that the condition is extremely prevalent, affecting as much as 25 per cent of some population groups,¹ the method of transmission of the disease is not completely known, consequently there is no specific method of prophylaxis. It is probable that the organism is transferred most commonly from one woman to another by contact with vaginal secretion present on toilet articles, toilet seats, bed pans, and similar hygienic mishaps. Transmission through still water pools is also a possibility. Since 5 to 27 per cent² of some groups of men are now known to harbor the organisms in the urethra or prostate, usually in very small numbers, transmission through sexual contact undoubtedly sometimes occurs. It is unlikely that infestation of the vagina occurs with trichomonads from the mouth or intestinal tract since the species of trichomonads from these sources differ morphologically and physiologically from *Trichomonas vaginalis*.

Although it is quite easy to obtain symptomatic relief from *Trichomonas* vaginitis, permanent cure of the condition is often extremely

difficult and prolonged. The trichomonads can be readily killed in the laboratory by simple drying or by exposing them to relatively low concentrations of a great many antiseptics or common laboratory reagents.⁹ Even in the vagina the organisms are rapidly destroyed on contact with a great many therapeutic agents. Unfortunately, however, occasional organisms can "hide out" in folds of tissue in the vagina or introitus, in the cervical canal, in the cervical glands, in the urethra¹⁰ and Skene's glands, in the bladder and in Bartholin's glands. Within twenty-four to forty-eight hours after local treatment it is not at all uncommon to again find large numbers of the flagellates in the vaginal tract. Unfortunately it is not possible to reach these occasional organisms which are responsible for reinfestation by systemic chemotherapy. Sulfonamides given by mouth in adequate dosage and penicillin given by injection fail to destroy the organisms. It is, therefore, my studied opinion that the technic of treatment in these resistant cases is often far more important than the drug employed.

Symptomatic relief in almost all cases can be readily obtained by douching persistently twice daily with a simple acid douche, but only rarely will this effect a cure. Even the use of medicated douches containing permanganate, iodine, mercurials or other antiseptic is of no additional help in permanently eradicating the flagellates.

The use of acid vaginal jellies likewise affords symptomatic relief and persistent, twice-daily use cures some of the milder cases.

Sulfonamide jellies when used persistently will effect cures in perhaps a somewhat greater percentage of patients but in our experience have not been useful for the more resistant cases. The sulfonamide jellies are helpful particularly as an adjunct in those cases in which there are associated streptococcal infections. The sulfonamides per se are not highly trichomonadocidal.

Medicated suppositories are generally not as effective as the medicated jellies since they do not diffuse as effectively and frequently do not mix well with the vaginal secretions.

For local treatment of the vagina no technic works as well as the introduction of the drug to be used in powder form diluted with a drying base such as kaolin. Many such preparations are available including arsenicals such as aldarson, acetarsone and carbarsone, silver picrate, argyrol, mercurials, sulfanomides and numerous other antiseptics. Although I have a preference for the pentavalent arsenicals, particularly aldarson,¹¹ I have been able to obtain satisfactory results with a considerable number of the antiseptic powders diluted with kaolin if the method of treatment has been appropriate.

The essentials of obtaining a cure involve thoroughness, frequency and persistence of treatment. The entire vaginal tract should first be cleansed with saline, 5 per cent sodium bicarbonate or suspensions of kaolin to remove all secretion and mucus. Particular care should be given to the cleansing of the cervix and introitus and any folds or

tissue about the urethra. It is also helpful to dry the tissues of the lower genital tract with a stream of warm air. The powder to be used is then insufflated into the vagina by means of an efficient vaginal insufflator of which there are several available such as the Shelanski or Holmes vaginal spray. The material must be thoroughly dispersed over the entire vagina and some of it should also be blown over the tissues of the introitus. The powder is allowed to remain overnight and the following morning a simple cleansing douche is used. It is important that at the onset treatment should be given daily, preferably every day for five or six days. If it is not possible for the patient to be treated by the physician so frequently she may be taught to give the insufflations herself, while lying in the bathtub, taking *due precaution to avoid increasing the intravaginal pressure* by removing the vaginal guard from the insufflator. The treatment can be effectively and safely given by the patient on those days when it is not possible for her to see the physician. After the initial treatments, insufflations can be given every second day, then every three days and then at less frequent intervals depending upon her progress. The physician must of course guard against cumulative or toxic effects of the particular drug used.

Before treatment is started, particularly in patients who have been unsuccessfully treated previously, it is wise to make a careful search for flagellates in the cervix and urethra by obtaining material from these sources on a bacteriologic loop which is immediately suspended in salt solution and examined at once under the microscope. The urine sediment from a centrifuged catheterized urine specimen should also be thoroughly examined for organisms. In married patients with persistent infestation examination of the prostatic and urethral secretions may also be necessary to rule out the husband as a source of reinfection.

In all persistent or recurrent cases it has been our practice to keep the patient under treatment for three months. After the initial series of treatments, insufflations are given twice weekly and are increased to once daily for two or three days just before and just after menstruation, since this is the period when reinfections are most commonly noted. It has also been our custom to have the patients douche daily with an acid douche throughout the entire menstrual flow. In those cases in which reinfection appears to be coming from the urinary tract or from the tissues anterior to the vagina the patients are advised to powder between the labia with the same medicament that is used for insufflation. This is done three or four times daily. In addition, a urinary antiseptic is prescribed. We have found pyridium to be very satisfactory for this purpose, one tablet four times daily.

When the trichomonads have disappeared from the lower genital tract, it is very helpful in obtaining a permanent cure to restore the normal vaginal flora and acidity as rapidly as possible. This is particularly necessary since *Trichomonas vaginitis* is almost always associated with a Grade III flora. For this purpose we employ an acid vaginal

jelly and an acid douche which is used for several months on days when insufflations are not given. Another problem which sometimes complicates the treatment of some severe cases of *Trichomonas vaginitis* is marked sensitivity of the patient to many drugs. This is sometimes a true allergy but more often the sensitivity is due to the extreme inflammation of the parts. Severe burning, irritation and edema may occur in such individuals after treatment. In this event treatment for the next several days should consist of simple saline douches every few hours, and cold compresses to the labia. After the acute inflammation has subsided insufflations with kaolin alone should be started, and then small increasing amounts of drug gradually added at each treatment.

VAGINAL MONILIASIS

Infections of the vagina with monilia and related yeastlike fungi have received considerable attention in the past several years. The infection produces a vulvovaginitis which gives rise to severe itching of the parts often with swelling of the labia and dermatitis of the surrounding skin areas. The discharge is not profuse but has a characteristic thick, cheesy consistency. The vaginal mucosa is generally coated with "thrush" patches. The infection is quite common during pregnancy, occurring in as many as 10 per cent in some prenatal clinics, but it is much less frequent in nonpregnant women. It also has a tendency to occur quite commonly among diabetic women. A high carbohydrate content and increased vaginal acidity favor the growth of the yeastlike fungi, thus explaining the increased frequency in pregnancy and among diabetics. In pregnant women infection may be transmitted to the baby at the time of delivery, thus giving rise to "thrush" in the newborn. Infection of the nipples of lactating women is also occasionally observed.

Moniliasis is a persistent infection and difficult to cure particularly in pregnant women.¹² The hyphae of the fungi tend to grow well into the epithelial layers making it difficult to remove the thrush patches by simple cleansing. Moreover, the yeast cells and spores are not easily destroyed by antiseptics.

Treatment consists in the removal of all thrush patches by gently but thoroughly swabbing the vagina with a 5 per cent solution of sodium bicarbonate or a diluted solution of green soap. The entire lower genital tract is then gently dried with cotton balls or a stream of warm air. The entire mucous membrane, introitus and labia are then painted with an antiseptic solution. There is no question but that gentian violet, 1 or 2 per cent aqueous solution, affords the most relief from the itching and in controlling the infection. However, the disagreeable staining and messiness is a great disadvantage. A considerable advance has resulted from the introduction of a vaginal cream which combines a low concentration of gentian violet with quaternary ammonium salts and possesses no staining properties whatsoever. The

detergent effects of the quaternary salts permits the use of lesser concentrations of gentian violet.* Moreover, we have found that the use of a jelly or cream base alone even without any added medicament is helpful because it mechanically loosens the thrush patches from the vaginal mucosa and washes them from the vagina. Five cubic centimeters of the cream is introduced into the vagina twice daily. This is followed by the use of a mild alkaline douche, an example of which follows

	Gm. or Cc.
℞ Zinc sulfate	2.0
Menthol	2.0
Camphor	2.0
Sodium biborate	90
Sodium bicarbonate	90

Mix and label A teaspoon in 2 quarts of water as a douche.

If the vulvar skin has become infected with the fungus, persistent treatment of these areas with the gentian violet jelly or other fungicidal ointments may be necessary.

During pregnancy it is at times necessary to treat the patient off and on throughout the entire gestation. We have never seen this result in any harm. Following delivery these patients frequently make a dramatic spontaneous cure due to the rapidly diminishing supply of glycogen in the lower genital tract.

It should be borne in mind that the male can be infected with monilia resulting in rather severe balanitis. The male can also serve as a source for reinfection of the wife.¹³

FUSOSPIRILLOSIS (VINCENT'S INFECTION)

Vaginal infection due to Vincent's organisms are usually associated with and favored by uncleanness. Not infrequently they may result from abnormal sexual practices or autoinoculation from the mouth of women suffering with Vincent's infection of the gums. It also quite commonly occurs as a secondary infection superimposed on other ulcerated lesions especially those of a granulomatous character. The vaginal mucosa and introitus present a 'raw beef' appearance and frequently there are deep ulcerations. The discharge is usually profuse, yellow and foul. Similar infections may be produced by other types of spirilla and spirochetes.

In this condition it is essential to recognize and treat any underlying infection and then to institute effective hygienic measures. The fusospirochilosis generally responds rapidly to insufflation with an arsenical

* This preparation was generously supplied to us for clinical investigation in the form of Genteral Vaginal Cream by Ortho Pharmaceutical Corp., Linden, New Jersey (The active ingredients may be identified as methyl rosaniline (gentian violet), quaternary ammonium compound and glycerine in a suitable vehicle containing a parahydroxybenzoic acid ester as a preservative.)

drying powder such as that described for *Trichomonas vaginitis*, or frequent daily application of neoarsphenamine, 10 per cent in glycerin, or frequent applications of gentian violet. We have found the use of sulfonamide jellies or creams to be highly effective in the treatment of this condition and much more convenient than the previous methods. For this purpose we have used particularly a cream containing three sulfonamides* each of which becomes effective at different pH levels. Five cubic centimeters of the cream are introduced twice daily into the vagina and removed after eight hours by a simple cleansing douche.

Recent studies indicate that jellies containing penicillin are also effective in the treatment of this condition, as is penicillin given parenterally¹⁴

VULVOVAGINITIS IN CHILDREN

Vulvovaginitis in children is generally classified as "specific" when it is caused by the gonococcus or "nonspecific" when due to other causes. The nonspecific type of vaginitis in children may result from the introduction of foreign bodies into the vagina, local irritation from manipulation or tight clothing, uncleanliness or low grade infections with a variety of organisms. Because of the delicate nature of the epithelial lining of the vagina together with its neutral or alkaline secretion, this structure in little girls is especially susceptible to bacterial infection.

In the treatment of *gonococcal vulvovaginitis* the first essential is strict isolation in order to prevent contamination of the other children in the household or institution. Care should be taken to prevent infection of the eyes or spread of the infection to the rectum. The local use of antiseptics and douches which formerly required many months and sometimes years of persistent therapy to effect a cure have now been replaced by treatment with estrogenic hormone, sulfonamides or penicillin. Each of these methods possess certain advantages and disadvantages.

Estrogenic therapy may be given to cooperative children in the form of vaginal suppositories. A suppository containing 0.05 to 0.1 mg of stilbestrol is inserted each night into the vagina. This is continued for three weeks after which smears are taken at weekly intervals until three negative smears have been obtained. If a cure cannot be effected with two courses of estrogenic therapy it is usually better to proceed with either sulfonamides or penicillin in order to avoid inducing premature sexual changes.

In children in whom local treatment is not possible or feasible, stilbestrol may be given orally 0.1 mg daily for two to three weeks. If

* Triple-Sulfa Cream, generously supplied to us for clinical investigation by Ortho Pharmaceutical Corp., Linden, New Jersey, contains micronized "sulfa" drugs (identified as sulfathiazole, acetylsulfonamide and benzylsulfanilamide) in a suitable base, nonbuffered to permit optimal pH effectiveness for the "sulfa" compounds.

any tendency toward growth of pubic hair or tenderness of the breast is noted this type of treatment should be stopped at once

A high percentage of successful results can be obtained with estrogenic therapy in children. In refractory or recurrent cases, examination of the cervix with a cystoscope should be made and the rectum should also be examined for infection. If either of these structures is infected, treatment with sulfonamides or penicillin is indicated.

In a number of clinics treatment with sulfonamides is preferred from the onset. In other clinics estrogens are preferred in order to avoid sensitization to the sulfonamides. Sulfathiazole is the most commonly employed preparation for sulfonamide therapy. The generally recommended dosage is 0.5 gram per pound of body weight per day in four divided doses with an equal amount of sodium bicarbonate which is continued for seven to fourteen days never longer than three weeks.

Good results can also be obtained with sulfadiazine in half the dose for sulfathiazole.

Preliminary results with penicillin administered locally and parenterally indicate that it is highly effective and will probably prove to be a most valuable method of treatment.^{15 16} As yet the best method of administration and dosage requires further investigation.

In the *nonspecific infections* of children the most important factor is the removal of any underlying cause such as foreign bodies as sources of local irritation. The infection itself will generally respond to the use of antiseptics, suppositories or jellies used persistently through a number of weeks. In the more persistent or severe cases, treatment with the estrogens as described for the gonococcal cases will generally effect a rapid cure. Sulfonamide therapy is not generally indicated in the nonspecific infections.

whitish plaques on a red base which may be secondarily infected due to the patient's scratching. At times the secondary infection may be so pronounced that the condition may resemble follicular vulvitis. Diagnosis is made on the characteristic appearance of the lesion, finding sugar in the urine, and positive smears for the fungus. Culture may be necessary to identify the organism in unusual cases.

Treatment is aimed at eliminating the glycosuria plus the local application of 2 to 5 per cent aqueous solution of gentian violet repeated as often as at twenty-four hour intervals. This latter gives prompt and complete relief from the pruritus which is usually the patient's complaint. It is important to remember that the entire vulva and vagina must be treated with the gentian violet solution when it is applied, otherwise the condition will persist.

Condylomata Acuminata—These papillomatous lesions of the vulva, often improperly diagnosed "venereal warts," are not venereal in origin but are due to a virus. They may be found in association with venereal disease, and are to be differentiated from condylomata lata which are syphilitic in origin. Lesions may be few or many in number, vary in size from pin-point to several millimeters in diameter and height, and occur in crops on the vulva and in the vagina. They are sometimes seen in pregnancy and, if left alone, frequently disappear after the gestation has terminated, without treatment. When removal is necessary because of bleeding and irritation (they rarely undergo malignant change) excision using the electrocautery is probably to be preferred. Local applications are of no value.

Pruritus Vulvae—Itching of the vulva is one of the complaints often encountered in gynecologic practice. Sometimes its cause may be obvious, more frequently investigation will reveal its background, quite commonly no cause can be determined and we are wont to ascribe the complaint to some form of psychoneurosis. In this latter attitude we may be wrong, it is possible that we have not studied the patient sufficiently or observed her for a satisfactory period of time to make the correct diagnosis. The more common causes of itching involve the specialties of medicine, dermatology, urology, proctology, and gynecology. Accordingly the stubborn case should be studied from these angles. Diabetes, jaundice, rectal conditions and parasites, diseases of the urethra and periurethral glands, infections of the genital tract, atrophic and degenerative changes in the vulvar skin due to estrogen deficiency (?), the various dermatologic lesions which cause itching in other parts of the body, local allergy to vulvar pads, talcum powder and the like, and last but not least, poor hygiene—any can be a cause of itching of the vulvar skin. Thus investigation should include urinalysis, smears, examination of any discharge by the hanging-drop method to exclude trichomoniasis, rectal examination, pelvic examination, and a careful examination of the status of the affected skin itself. Moreover, the serologic examination should not be neglected.

Treatment will depend on whether the pruritus has its foundation in systemic or local factors. Medical causes are treated in the usual fashion. Local conditions are treated appropriately. Symptomatic relief is often afforded by removing discharges with cleansing douches (lactic acid solution, U.S.P.—1 teaspoonful to 2 quarts of water), calamine lotion with phenol, and eucupin and benzocaine ointment are helpful, any of the recognized forms of treatment for trichomoniasis (floraquin, ceepryn, silver picrate, and so forth) may be used, gentian violet in 2 to 5 per cent aqueous solution is specific for fungous infections, estrogen cream (stilbestrol 30 mg to the ounce of vanishing or similar cream) or oil for localunction gives prompt relief to some patients with atrophic or degenerative changes of the vulvar skin possibly associated with estrogen deficiency, poor hygiene can be corrected by proper advice and the proper toilet following urination and defecation can be impressed on the patient. The use of x-rays in treating pruritus of undetermined etiology sometimes gives relief. When relief occurs it is usually prompt and follows the first few exposures. Total exposure should not probably exceed one erythema dose, and this should be given in divided dosage at two to three day intervals by a competent radiologist, or at least under his immediate supervision, in order to avoid dermatitis from the x-rays.

Kraurosis Vulvae—Kraurosis vulvae and leukoplakia of the vulva are two conditions often intimately associated in the minds of many physicians. The only thing which both conditions actually have in common is that patients having either condition complain equally bitterly of the pruritus which frequently accompanies the conditions.

Kraurosis vulvae is a term of indefinite meaning in the literature. It is intended to mean a shrinking or shriveling of the vulva. Actually there is a definite atrophy of the vulvar structures—a flattening of the labia majora and a thinning of the skin which may appear colorless, pale or reddened and often exhibits fissures. The patient's only complaint on occasion may be dyspareunia on entrance due to the constriction of the introitus secondary to the atrophy of the tissues. The pruritus causes scratching and as a result secondary infection is sometimes seen. The cause of the condition is unknown but because it is seen during the period of supposed waning ovarian function and in the postmenopausal state, some authorities feel that it may be associated with estrogen deficiency. Various treatments have been suggested but the most successful has been the use of local oestrogens in various forms. Fairly prolonged relief may be obtained by producing vaginal blood stasis by means of tampons soaked in oil soluble steroid hormones. Fairly prolonged relief may be obtained by producing vaginal blood stasis by means of tampons soaked in oil soluble steroid hormones.

present, may cause dermatitis in unskilled or even skilled hands Ultimately, in patients with dyspareunia and pruritus, the treatment of choice is vulvectomy Asymptomatic atrophic changes may be treated with conservatism, as a matter of fact they require no treatment

Leukoplakic Vulvitis—Better called *leukoplakia of the vulva* because leukoplakia may be observed on any epithelial surface, leukoplakic vulvitis is a local or diffuse whitish thickening of the skin of the vulva and perianal areas, with or without the formation of fissures The condition often seems to develop in the perineal and perianal areas, spreading forward to include the labia and clitoris and backward to involve the gluteal cleft. Pruritus is the chief complaint again, but the condition may be entirely asymptomatic Secondary infection may be present following scratching The cause of this condition is not known

Treatment by hormones (estrogens and androgens) as advocated by some clinicians has not been generally accepted because the late Doctor Taussig, in his monumental work on this condition, showed that over 50 per cent of the patients he treated for carcinoma of the vulva suffered from leukoplakia of the vulva before the carcinoma developed Accordingly, the condition has become recognized as a definite precancerous lesion and the treatment of choice, either in symptomatic or asymptomatic cases, is vulvectomy

ULCERATIVE AND HYPERTROPHIC DISEASES OF THE VULVA

Hypertrophic ulcerations of the vulva, some of which are associated with the development of fistulas, require careful study for their diagnosis and differentiation one from another Included under this heading are chancroid, lymphopathia venereum, granuloma inguinale, tuberculosis, syphilis, fusospirochetosis and carcinoma A definite routine of study is necessary when any such lesion of the vulva is encountered

Chancroid—Chancroid, a venereal disease seen more often in men, is associated with a lack of cleanliness The local lesion consists of a painful pustule which ulcerates superficially leaving a reddish granular base without surrounding induration and extremely painful to touch The lesions may be multiple due to autoinoculation Inguinal bubo develops early and is often unilateral when present It may slough or rupture spontaneously and drain freely for some time The infection does not become systemic The causative organism is the streptobacillus of Ducrey which can be identified by smear and culture The intradermal injection of killed organisms produces a local reaction (Ducrey test) which is diagnostic

Treatment consists of the use of sulfanilamide both locally and systemically Allantomide or sulfallantoin cream or jelly applied locally favors healing of the ulcerations Buboec when present are preferably treated early, before rupture, by aspiration Penicillin has not yet been used sufficiently to permit an estimate of its value in treatment

Lymphopathia Venereum—More commonly known as *lymphogranuloma inguinale*, this is a venereal disease thought to be due to a filtrable virus. It is seen more commonly among the colored race although its prevalence in white women is on the increase. There are two forms—the one associated with the formation of inguinal buboes with or without draining sinuses is more common in men, and the other which predisposes to rectal stricture seems to be more common in women. These two types of lesions are dependent on the peculiarities of the lymphatic structures of the genitalia of the two sexes. The initial lesion may be a small or large ulceration, superficial or deep, occurring on any portion of the vulva or vagina. If it occurs in the anterior portion an infection of the first type above will develop, if in the fourchette, perineum or perianal area or posterior portion of the lower vagina, an infection of the latter type will result. Diagnosis is made by the Frei test—the intradermal injection of the patient with a killed suspension of the virus collected from the bubo or prepared from infected mouse brain or chick embryo. A positive test after forty-eight hours consists of an elevated firm papule surrounded by an area of erythema. The papule may vesiculate or ulcerate in very strongly positive reactions.

Treatment is unsatisfactory. Sulfanilamide has been used with some good effect but most results are poor. It is considered best not to incise the buboes if they develop, but when liquefaction has occurred the contents can be aspirated. If rectal stricture develops, obstruction is often a late eventuality and may require colostomy. Hypertrophy of the vulva may occur from blockage of the lymphatics and may require vulvectomy.

Granuloma Inguinale—This disease involves the vulva, groins, perianal region and inner sides of the thighs. It is more common in Negroes, and is seen in both tropical and temperate zones (at one time it was thought to be a tropical disease). The initial lesion is a small papule which ulcerates to form a soft nontender elevated granulating ulcer of red color. The duration of the disease is unknown but it apparently requires several years for development to the proportions described above. Inguinal adenopathy is unusual. There is a general absence of systemic signs and symptoms. Scarring as a late manifestation may cause hypertrophy of the vulva through obstruction of the lymphatic channels. Diagnosis is made by finding the Donovan bodies in smears taken from the granulomatous lesion and in biopsy specimens.

Treatment is not satisfactory, tartar emetic is given intravenously and fuadin intramuscularly over a prolonged period of time. Recently a case was reported with apparent extragenital lesions of arthritis and osteomyelitis in which treatment with tartar emetic and in addition with sulfadiazine was without effect. Occurrence of such findings should negate the impression that systemic signs and symptoms are not present. Reports on the use of penicillin are not available to date.

Tuberculosis of the Vulva—Vulvar tuberculosis is due to a local infec-

tion with the tubercle bacillus. Infection may take place through a break in the skin or through the blood or lymph stream. The lesion is usually a chronically ulcerating growth with elevated edges and an irregular grayish-red granular base with some surrounding infiltration. The ulcers may be superficial or deep, even causing fistulous tracts connecting with the bowel, bladder, or the urethra. The diagnosis is made by making smears and taking a biopsy after suspecting the presence of the condition. The microscopic picture is necessary for certain diagnosis, but even here, granulomas of the vulva due to foreign bodies such as talcum powder may give a microscopic picture which can prove confusing even to the experienced observer.

Treatment will vary with the nature and extent of the lesion, if it is purely local, excision is preferable, if it is too extensive for complete excision, then x-ray treatments are preferable to the application of radium locally because of the sloughing effect of the latter. In the presence of general infection local treatment is without effect except as a palliative.

Syphilis—In the vulva, syphilis may appear as either the primary, secondary or tertiary lesion. The primary lesion or chancre may be anywhere but is usually on the labia, vestibule or fourchette. It is a small, elevated, firm, nontender ulceration with a grayish base which exudes serum when the slough is removed. It may be single or multiple due to autoinoculation where folds of vulvar skin are in apposition. Diagnosis is made by darkfield examination which may have to be repeated. The secondary lesions may appear as condylomata lata or mucous patches. Darkfield examination is used here for diagnosis but in the event it is negative, biopsy should be made. The serology is usually positive by the time the secondary lesions manifest themselves. The tertiary lesion or gumma is unusual and for diagnosis biopsy of the edge and surrounding tissue is necessary together with serologic examination. Treatment is standard.

Fusospirochetosis of the Vulva—Fusospirochetosis or Vincent's infection of the vulva is occasionally seen. Whether this is a primary or secondary infection is not usually clear. The vulvar skin is edematous and macerated with few or many sloughing, acutely tender ulcerations which are associated with a fetid, acetic discharge. Smears from the ulcerations show the fusiform bacillus and the spirillum. The source of the infection is not always clear, but the use of saliva from an infected mouth as a lubricant during coitus has been considered as a possible mechanism.

Treatment is both local and general. Bed rest is desirable because of the systemic reaction which is often present and the severe pain. Sodium perborate or potassium permanganate douches help local hygiene. Arsphenamine or mapharsen locally and intravenously help to bring relief more quickly. Penicillin is reported to be very effective locally in oral infections and should help greatly here.

ROUTINE OF STUDIES TO WHICH PATIENTS WITH HYPERTROPHIC ULCERATIONS OF THE VULVA SHOULD BE SUBJECTED AND THEIR SIGNIFICANCE

	Etiology	Darfield	Secret	Culture	Serology	Biopsy	Skin Test	Therapeutic Test
Chancroid	Streptobacillus Dreyer	Excludes syphilis.	Positive value.	Difficult but of positive value.	Negative.	Excludes carcinoma.	Negative Dreyer test excludes.	Sulfonamides locally and systemically.
Lymphopathia venereum, etc.	Filtrable virus.	Excludes syphilis.	No value except to exclude other conditions.	Shows only second ary invaders.	Negative Complement fixation test with chick anti ven is specific.	Positive value, also excludes carcinoma.	Negative Fied test excludes.	Vaccine plus sulfonamides of ? value.
Gonorrhea (agutale.	Intra-cellular Donovan bodies are scarce or absent.	Excludes syphilis.	? value. Donovan bodies may be found.	No value, secondary invaders only.	Negative.	Most important also excludes carcinoma.	No value.	Therapeutic, sulfonamides are of value.
Tuberculous.	Tubercle bacillus.	Excludes syphilis.	? value.	? value and difficult animal inoculation.	Negative.	Most important also excludes carcinoma.	Negative value only.	
Syphilis.	Spirochaeta pallida.	Positive value.	Excludes leprosy, chertal organisms.	No value.	Positive Wassermann and Kahn.	Positive value, also excludes carcinoma.	? value.	Antiseptics specific.
Fusospirochaetosis (Vincent's)	Fusiform bacillus and spirillum (brock coli)	Doubtful value.	Positive value genital violet stain.	Most valuable.	Negative.	Excludes carcinoma.	Negative Fied and Dreyer of value to exclude.	Antiseptics help. Penicillin very effective locally.
Carcinoma.	Unknown.	Excludes syphilis.	Washings stained by Papanicolaou's technique may be of value.	No value.	Negative.	Only positive means for diagnosis.	No value.	

Carcinoma of the Vulva.—Vulvar carcinoma is the third most frequent form of genital cancer in the female, being preceded only by the uterine and ovarian forms of malignancy. It may be primary or secondary, the former being by far the most common. It is a disease of advanced age since most reported cases have occurred in the seventh decade of life. The more common sites of origin are the labia, clitoris, vestibule and urinary meatus, and rarely Bartholin's gland. Histologically the growth may be epidermoid or adenocarcinoma depending on the site of origin, the former being more usual. The condition begins as a small nodule, asymptomatic at first, which gradually increases in size and eventually ulcerates. This is what usually brings the patient to the doctor. The diagnosis, when suspected, is confirmed by biopsy. Carcinoma of the vulva, except the clitoris, develops slowly.

Most cases occur in the anterior portion of the vulva from which the lymphatic drainage is through the inguinal nodes. When recognized early, carcinoma of the vulva can be cured by radical vulvectomy and excision of the superficial and deep inguinal glands (Bassett's operation) as advocated by Taussig who claims above 50 per cent cures. Secondary carcinoma, although rare, may be seen and represents metastasis from other genital cancers or chorioepithelioma. The treatment is palliative.

THE PROBLEM OF SEXUAL DISSATISFACTION

The role played by the physician in the management of the problem of sexual dissatisfaction, and the related problems of dyspareunia and vaginismus, is that of confessor and adviser. Usually the patient is distraught with fears—fear of the permanency of her marriage, fear that she is not a good wife, and so forth and finally consults a physician in desperation. She does not blurt out her story in so many words, usually it is a long-drawn-out recital of vague pelvic complaints for which the physician can find no basis in actual pelvic disease. Then when he explains that he can find no pathologic changes, and solicitously inquires just what did cause her to come to his office, the true story slowly emerges. Haste is dangerous at this point, it must be remembered that from the patient's viewpoint she is making a confession. The story unfolds slowly because often in the patient's mind it is a confession of her sexual inadequacy. Most often we know that this is a complex built up as the result of a thoughtless or unadaptable husband who is more concerned with himself than their mutual well-being. Here the physician is confronted with a problem which he can solve by using a combination of sympathetic understanding and judicious questioning. The patient cannot be hurried—adequate time must be allowed for her to collect her thoughts and express in her own way the background of her troubles. If for any reason the physician is unable to give such a patient sufficient time, he had better refer her

to someone who is willing and able to spend the necessary time with her, since a rebuff at this stage may be sufficient to prevent her from making a second attempt to straighten out her difficulties

In order to arrive at some idea of the cause of the patient's distress, careful questioning concerning the first sexual experiences is necessary. Often here will be found the answer. Trauma on the part of a young husband ignorant of the elements of coitus, haste because he does not realize that in woman passion must smolder before it bursts into flame, a total lack of consideration on his part during the formative period of the intimacy of their marriage, a warped picture of the significance of sexual relations in marriage on the part of the wife—any or all may be the factor(s) which must be sought out and corrected by suggestion by the physician. All of these factors could be eliminated by a short postmarital check-up by the family physician, in case the couple had not the advantage of a premarital consultation with a physician (which probably would have prevented the difficulty from ever having developed)

Once the problem has been stated and some notion of the cause established, the most desirable move next is a frank talk with the husband, apart from his wife. Some questioning will provide the physician with an idea of his sexual knowledge and experiences (and the most experienced are not the best informed when the satisfaction of two persons is to be considered') and suggest what information should be given. Usually it is well to explain briefly by word and picture or diagram the male and female anatomy and physiology to both parties, either alone or together. Then explain to them why sexual relations are necessary—first for the purpose of procreation and secondly for their mutual pleasure and satisfaction. Allow them to ask questions, if they wish, and answer them in a clear, understandable language. One of the most important points to impress on the husband is the difference in response of male and female to stimulation. In the average male suggestion alone is sufficient stimulation while in the female suggestion plus caresses and repeated stimulation, sometimes over a relatively prolonged period of time, are necessary. Impress and reimpres on the husband that self-control is necessary and remind him that because he may be ready, or even anxious, to consummate relations his wife may not have reached the stage where the act will be pleasurable for her. Explain that at this point the success or failure of the purpose of the act is in the balance. The occurrence of repeated failures on the part of the wife, because of the selfishness of her husband, is part of the background in this problem of sexual dissatisfaction. It is only a short step to the conviction in the mind of the wife that she is sexually inadequate. From there on the number of complaints, real or imaginary, are myriad and the seed of discontent on the part of either husband or wife, or both, may have been sown. I am convinced after questioning many hundreds of married women and their husbands,

that selfishness combined with a lack of consideration and frequently a total ignorance of the elements of coitus on the part of the husband is a far more common cause of sexual dissatisfaction than any supposed or imaginary sexual inadequacy on the part of the wife. There are no more grateful patients than those for whom a problem of this type has been solved by the physician.

The essentials of success in the management of these problems are first of all a sympathetic understanding by the physician of the true situation which exists, tactful questioning of both husband and wife after each has told his or her story to the physician, a careful explanation of the purposes of sexual relations, a brief explanation of the male and female anatomy to both parties, and finally a note of caution to the husband that the old proverb "haste makes waste" applies even to such things as sexual relations.

proliferation and differentiation of the granulosa cells and ingrowth of the theca lutein cells

The Progesterin Phase—In a dual capacity the corpus luteum continues the elaboration of estrogenic principle and also produces another hormone, termed progesterin. This transforms the estrogen primed endometrium into a premenstrual state suitable, should an ovum become fertilized, for nidation.

In this phase the mucosa becomes differentiated into three distinctive layers (1) a compact surface layer, (2) an intervening spongy layer, and (3) immediately overlying the myometrium a basal layer. Marked secretory activity of the surface cells, but more particularly those of the glands, is evident. The epithelium lining the glands is composed of large cells with basal nuclei.

The stroma also shows specific changes. A thin layer of lightly stained large polygonal stroma cells with large round nuclei forms the compact layer of the mucosa. These cells, however, are not equally developed in all areas. They are not unlike the decidual cells of early gestation and are termed pseudodecidual cells. In the middle or spongy layer are found characteristic markedly tortuous glands, closely packed, but separated from each other by strips of stroma cells. The gland lumen is filled with secretion. The basal layer is unchanged. The histology of the progesterin endometrium is similar to that of a two weeks' gestation and only the absence of chorionic villi distinguishes it.

The true premenstrual stage is the period from the cessation of actual production of progesterin to the onset of bleeding and is only about forty-eight hours in duration. The coiled endometrial arteries constrict at the base with a peripheral ischemia and the stroma of the endometrium becomes dehydrated. Subepithelial hematomas appear coalescing into lacunae which begin to bleed into the lumen.

Types—There are, according to the modern concept of menstruation, two different types of a menstruating mucosa.

1 *Normal*—In this type, the functional layers (compacta and spongiosa) are dismantled, leaving a raw wound, the base of which is formed by the altered basilar layer. This is the most common type.

2 *Pseudomenstruation*—In this form, menstruation occurs from an inactive or almost resting mucosa. There is no evidence of the premenstrual phase in the mucosa, uterine bleeding occurring from an estrogenic endometrium. This periodic bleeding is not a genuine menstruation, because it is not associated with the characteristic preparatory endometrial changes nor with extensive endometrial desquamation. This inadequate preparation of the endometrium makes proper implantation of the fertilized ovum impossible and explains many cases of sterility in regularly menstruating women.

Other possible causes of pseudomenstruation besides failure of ovulation are imbalance of the two ovarian hormones, estrogen and progesterin, and a uterus which fails to respond to normal ovarian stimulation.

In studying cases of menstrual disorders, a diagnostic premenstrual uterine curettage is important in that it shows the end result of the effect of both estrogen and progesterone activity on the endometrium. If the endometrium is normally responsive the type of ovarian dysfunction can be determined. Day-to-day vaginal smears also determine estrogenic effect and cyclic ovarian changes. The probable date of

ovulation can often be elicited as well as the effectiveness of therapy. The interpretation of the smear consists in finding cells from the basal vaginal layer indicative of estrogen deficiency or cornification of cells from the superficial vaginal layer showing estrogen activity.

Etiology.—As the result of anterior pituitary stimulation of the ovaries, estrogen is gradually concentrated in the endometrium. The premenstrual saturation of the follicular hormone in the uterine mucosa finally causes regressive endometrial changes with resultant bleeding.

The role of the corpus luteum hormone is a passive one of maintaining the endometrium intact. Progesterin is capable of nullifying the terminal effects of estrogen described above. When the corpus luteum regresses in the absence of pregnancy, the saturation effects of estrogen on the endometrium are uninhibited and bleeding results. This involution of the corpus luteum is probably brought about as increasing quantities of estrogenic hormone produced by the ovary gradually inhibit the pituitary gland which, therefore, withdraws its stimulation of the corpus luteum about two days before actual bleeding with resultant menstruation.

In addition, an undetermined "bleeding factor" present in the endometrium of the adult woman only appears to be essential for the onset of menstruation. Thus a child will rarely menstruate even though large quantities of both ovarian hormones are administered. Furthermore, women are occasionally encountered who do not menstruate, although they have a normal amount of estrogen in the blood and urine and an active secretory endometrium, indicating, perhaps, an absence of this so-called bleeding factor.

AMENORRHEA

The term amenorrhea refers to a marked diminution or complete absence of the menstrual flow. It is classified as primary or secondary. The former refers to a total failure of menstruation to appear, and the latter to a cessation of the cycle after its establishment.

Oligomenorrhea is applied to menstruation occurring at intervals of two or three months. Hypomenorrhea refers to regular though scanty menstruation.

Physiological amenorrhea denotes the absence of menstruation during some physiologic process. Pathological amenorrhea refers to the absence of the period as a result of some anatomical disorder.

Etiology.—**PHYSIOLOGICAL AMENORRHEA**—Menstruation is nearly always absent during pregnancy and lactation. It is absent before the establishment of puberty, and after the menopause.

PATHOLOGICAL AMENORRHEA—The causes of pathological amenorrhea are both general and local.

General Causes—1 **Constitutional Diseases.**—The most common constitutional disorder associated with an absence of the menstrual flow is

advanced pulmonary tuberculosis The primary anemias are generally associated with the condition, as may be diabetes, chronic nephritis, and tuberculous infections other than those involving the lungs It may result from profound nervous shock, and it occurs in the advanced stages of organic nervous disease In Manila it was recently reported that in many patients the menses stopped abruptly after the first bombing or soon after internment and before a food deficiency could have any effect.

2 Acute Infectious Diseases—Amenorrhea is often present during convalescence from the acute exanthemas, typhoid fever, malaria and influenza

3 Climatic Influence—Exposure to wet and cold, with sudden chilling of the body or a simple change of environment may result in a temporary check of the menstrual process

Local Causes—1 Primary—The most common local cause of amenorrhea is congenital ill-development of the organs fundamentally concerned in menstruation Usually the uterus and ovaries are involved, the hypoplastic alteration in the uterus being secondary to that in the ovaries Hypoplasia of the latter organs may not be congenital, but may represent some pathologic alteration which had its inception in early adolescence Irregular development of the genital organs, especially an imperforate hymen or stenosis of the vagina or cervix, results in a failure of the menstrual flow to appear

2 Secondary—Radical curettage or prolonged radium treatment may cause amenorrhea by destroying the endometrium

Follicle cysts of the ovary as a cause of amenorrhea are not infrequent These may result from the inability of the ovum to penetrate an inflamed, thickened tunica albuginea, or more commonly, may be due to an insufficient hormonal stimulation from the anterior pituitary gland, so that the follicle fails to rupture If the follicle does not rupture, it becomes either atretic or distended with fluid and forms one or more retention cysts Occasionally these cysts elaborate a sufficient quantity of estrogenic hormone to produce prolonged menstrual bleeding

Endocrinopathic Causes—Disorders of the endocrine system may be associated with amenorrhea and this is especially true of the anterior pituitary gland and ovaries These disturbances may be classified as 1 Primary Pituitary Deficiency—Primary deficiency of the anterior pituitary lobe is by far the most common form of endocrine disturbance encountered Generally speaking, this condition, if not sufficiently severe to suppress totally ovarian function, is usually one of a mild Frohlich's syndrome (adiposogenital dystrophy) Clinically, these patients are rather short in stature and show distinct stigmas of underactivity of the hypophysis, manifested first by a characteristic mammary mons girdle obesity due to associated involvement of the hypothalamus, secondly by hypertrichosis with masculine distribution

of pubic hair, and thirdly by genital hypoplasia with menstrual derangement.

2 **Primary Ovarian Failure (Primary Hypogonadism)**—Primary ovarian failure is due to inherent deficiency of the internal secretory portion of the ovary independent of the secondary effects of the diminution of function of other glands, notably the pituitary and thyroid. Clinically, these patients present a marked contrast to those of the hypopituitary type. They represent the superlatively feminine type. They are emotional to excess, underweight, visceroptotic and intolerant to food. They experience gastrointestinal spasticity, irritability of the nervous system and dysmenorrhea.

Hypoplasia of the genital organs and irregular menstruation, or amenorrhea, are constant observations. Hormone studies reveal a uniformly low estrogenic level in the blood premenstrually. The most significant finding, however, is a demonstrable quantity of anterior pituitary gonadotropic hormone in the blood and urine in about 50 per cent of the patients.

3 **Thyroid Derangement.**—It is well known that the ovary depends on thyroid secretion to increase its chemical reactions. However amenorrhea occurs more frequently with hyperfunction. Hypothyroidism is more often associated with an excessive flow.

4 **Uterine Factor**—Amenorrhea sometimes is noted in patients with a normal level of blood and urine estrogen. In these women the uterus becomes atrophic and fails to respond to normal or increased ovarian function. Occasionally, however, one is surprised in obtaining on curettage a normal secretory endometrium. In these patients the absence of the so-called bleeding factor is, perhaps, responsible for the amenorrhea.

Many of the disturbances associated with amenorrhea of endocrine origin are due to worry and anxiety over the nonappearance of the menses rather than to any direct effect of the amenorrhea itself. Most symptoms are relieved when the patient is reassured that amenorrhea does not mean the "retention" of harmful products.

Treatment—The treatment involves the employment of measures to correct the cause. We shall confine ourselves chiefly to a discussion of the endocrine therapy.

QUANTITATIVE HORMONAL ASSAYS AS GUIDE TO TREATMENT—Quantitative hormonal assays of anterior pituitary and ovarian excretion in the urine gives us the best means of determining endocrine function and therapy in both amenorrhea and dysfunctional uterine bleeding. The following hormonal assays are available for this purpose.

1 **Gonadotropic Hormones**—Elaborated by the anterior pituitary gland they stimulate the ovaries by means of two specific hormones: the follicle-stimulating and luteinizing hormone. In addition chorionic gonadotropin, somewhat resembling the above is produced by the chorionic cells of the placenta. A twenty-four hour urine specimen is collected and the proteins precipitated by alcohol. Bio-assay is made by injection into infantile mice. These assays are of

value in determining pituitary dysfunction in menstrual disorders and whether we are dealing with primary pituitary failure or primary hypogonadism

2 *Estrogenic Hormones*—For determination of estrogen in the urine, the urine is first hydrolyzed by boiling for fifteen minutes with 5 per cent hydrochloric acid or sulfuric acid. This releases about 95 per cent of the estrogenic hormone present by converting the inactive to active estrogen. During active sex life, except during pregnancy when there is a huge increase, a woman normally excretes in the urine 150 mouse units of estrogen in twenty-four hours.

There is a rise in estrogen at the time of ovulation followed by a drop and then another rise premenstrually. The highest concentration is noted at the end of the premenstrual stage. A modification of the Allen-Doisy test is usually employed in which the extract is injected into castrated adult mice or rats and varying degrees of vaginal estrus observed.

These are accurate and practical tests to determine the level of ovarian activity. They are of special value in the diagnosis of functional sterility in regularly menstruating women. At the premenstrual phase of the cycle, close to 90 per cent of normal fertile women show a demonstrable quantity of the hormone. In regularly menstruating sterile women, without pelvic disease, a positive reaction is much less frequent, thus indicating a deficiency of estrogenic production.

3 *Progesterone and Its Excretion Product, Pregnandiol*—Progesterone is metabolized in the liver and excreted in the urine as a water-soluble compound, sodium pregnandiol glycuronate. Pregnandiol has no biologic action but can be determined in the urine by the gravimetric method of Venning and Browne. In menstrual disorders, the presence of pregnandiol in the urine immediately after ovulation in amounts of 3 to 10 mg is indicative of a normal corpus luteum and ovulation.

4 *Androgens and 17-Ketosteroids*—A woman normally excretes about three-fourths as much androgen as the male. This is derived from the adrenal cortex. Biologic assay is difficult. Chemical assay for 17-ketosteroids is employed instead. The term "17-ketosteroids" refers to those steroids possessing a ketone group on the 17th carbon atom. The principle 17-ketosteroids that occur in the normal human urine are androgenic. Therefore they serve in the female as an index of adrenal function.

In female hypogonadism, the 17-ketosteroids may be normal in primary ovarian failure but diminished if due to pituitary deficiency.

In considering endocrine therapy, functional amenorrhea and menorrhagia can practically be discussed together since both represent varying degrees of the same endocrine disturbance. To the woman suffering psychically from amenorrhea of functional origin, it makes no difference whether she is bleeding from a proliferative or a progestational endometrium. The mental relief is the same. To the woman, however, in whom amenorrhea and sterility coexist, the cure of the latter depends in great measure upon a physiological cure of the underlying uterine ovarian deficiency. We will therefore consider in order the specific therapeutic value of (1) the gonadotropic hormones, (2) the estrogens, (3) progesterone, (4) androgens (testosterone), (5) thyroid.

1 *Gonadotropic Hormones*—The gonadotropic hormones available are as follows:

(a) *Hypophyseal Gonadotropin*—Extracted from fresh anterior

pituitary glands of sheep and horse, it contains both follicle-stimulating and luteinizing fractions. Its value lies, therefore, in its ability to stimulate a hypofunctioning ovary if due to a pituitary gonadotropic deficiency. It does not cause ovulation. Injections should be stopped after three weeks of the cycle and after three months of cyclical administration due to the danger of producing follicle cysts of the ovary. It is employed in amenorrhea and in functional uterine bleeding due to deficient luteinization. The commercial preparations available contain 25 to 500 rat units per cubic centimeter.

(b) **Equine Gonadotropin**—Extracted from the serum of pregnant mares, it is mostly a follicle-stimulating hormone and only slightly a luteinizing hormone. In amenorrhea associated with genital hypoplasia, it is administered in doses of 200 to 400 I.U. intramuscularly three times a week for two weeks followed by a two weeks' rest or a course of chorionic gonadotropin.

(c) **Chorionic Gonadotropins**.—Extracted from the urine and placenta of pregnant women, its biologic effect is chiefly a luteinizing one. It has no value in the treatment of amenorrhea unless preceded by hypophyseal gonadotropin in the first two weeks to cause follicle maturation. Then it may be given as 500 I.U. daily for two weeks.

In uterine bleeding due to progesterone deficiency 500 I.U. are recommended three times weekly.

(d) **Combined Hypophyseal and Chorionic Gonadotropin**.—This product is indicated in any disorder due to failure of ovulation. One cubic centimeter is given intramuscularly three times a week. Not more than 5 to 10 cc. should be given a month due to the danger of producing hemorrhagic and cystic ovaries.

2 **Estrogens**—The estrogenic hormones are both natural and synthetic. Standardization is in terms of international unit defined as the estrogenic activity of 0.001 mg. of estrone, as rat unit—1 R.U. being equivalent to 5–10 I.U., and by weight, in milligrams of active substance. It is administered intramuscularly, orally, locally and in decho-lin may be given intravenously.

For amenorrhea 50,000 I.U. are given three times weekly for two weeks, followed by a course of progesterone and repeated monthly.

The chief value of estrogens is to stimulate uterine growth in patients with primary ovarian deficiency. At best it is only substitution therapy. Its advocacy in functional bleeding is questionable except where an atrophic endometrium is present. Ovulation may be inhibited and bleeding stopped for a while but withdrawal bleeding may be severe especially in a patient with a hyperplastic endometrium.

Danger of prolonged usage inhibiting the pituitary and ovary should be emphasized.

3 **Progesterone**—This may be administered intramuscularly or orally as pregnenolone, 1 mg. being equivalent to 0.2 mg. of progesterone by injection.

Secondary amenorrheas respond after the administration of 20 mg of progesterone given daily for three days (Zondek). It is better, however, especially if the amenorrhea is of longer duration than six months to prime the endometrium first with large doses of estrogen. Zondek recommends 1 mg of alpha-estradiol given together with 10 mg of progesterone daily for five days.

Progesterone may be of value in functional uterine bleeding if due to a progesterone deficiency such as is found in cases of hyperplasia of the endometrium. Ten mg are injected twice weekly for the last two weeks of the cycle.

4 *Androgens*—Testosterone may be given intramuscularly, sublingually, as a pellet under the skin or orally as methyl testosterone which is one-fifth as effective as the intramuscular injection. The danger of producing hirsutism should be kept in mind and may probably be avoided by limiting the dosage to 300 mg per month and discontinuing it as soon as acne is evident. It is of great value in inhibiting some of the effects of estrogen on the endometrium and myometrium and in inhibiting the gonadotropic function of the pituitary. It tends to produce an atrophic endometrium. It is of special value, therefore, in functional uterine bleeding, 25 mg are injected three times weekly.

5 *Thyroid*—This is a valuable adjuvant in the treatment of functional amenorrhea and bleeding and may be used even when the basal metabolism is normal, or slightly subnormal. The administration of desiccated thyroid tissue, 0.09 or 0.13 gm (1½ or 2 grains) daily, tends to increase cellular activity throughout the entire body, including the endocrine glands. In addition, it has been shown that thyroid extract neutralizes the action of estrogenic substance on the endometrium. This may explain the temporary beneficial effect of thyroid therapy in functional uterine bleeding when prolonged and unantagonized activity of estrogenic substance on the endometrium is the immediate cause of the abnormal uterine hemorrhage.

Prostigmine has been used in the treatment of delayed menstruation. One mg is injected on three consecutive days. Estrogenic substances release acetylcholine in the uterus which produces local hyperemia. Prostigmine is a nonspecific agent with a similar property of potentiating the action of acetylcholine. If no menstrual flow occurs within seventy-two hours after the last injection a tentative diagnosis of pregnancy is made.

Insulin—This drug may restore normal menstruation in some patients, especially those who are underweight and suffering with primary ovarian underactivity.

Irradiation Therapy—Low dosage irradiation of the pituitary gland and ovaries is a valuable measure in the treatment of functional amenorrhea as well as menorrhagia of endocrine origin. The therapeutic action of irradiation is generally attributed to a transitory or permanent increase in cellular activity of the ovary. X-ray stimulation of the ovaries

is contraindicated in the absence of a subthreshold quantity of blood estrogen, as it may induce permanent amenorrhea.

Ovarian irradiation is only partially effective when the ovarian hypofunction is secondary to hypophyseal or thyroid underactivity. In such instances irradiation of the pituitary appears to have an adjuvant value. Low dosage irradiation of the pituitary gland and ovaries affords the best results in the treatment of menstrual disturbances with functional sterility associated. Strict adherence to the technic of the roentgenologist is most essential, i.e., from 50 to 80 roentgen units or about 10 per cent skin erythema dose being given once a week over a period of six weeks. The one menstrual disorder that almost invariably fails to respond is hypomenorrhea (scanty flow) in regularly menstruating women. The cause of the menstrual deficiency in these patients is apparently within the uterus itself.

MENORRHAGIA

This term is applied to excessive menstruation, or to an undue prolongation of the flow. It may be anatomical or functional, the latter diagnosis being arrived at by exclusion.

Etiology—ANATOMIC TYPES—The anatomical causes of menorrhagia are either general or local. These may be considered under the following:

General Causes—1 **Blood Disease**.—In patients with a hemorrhagic tendency menorrhagia is commonly present. It may be the first symptom of purpura hemorrhagica, leukemia, aplastic anemia, and Hodgkin's disease.

2 **Systemic Disease**.—Disease of the cardiovascular apparatus, kidney or liver disease, resulting in a tardy return circulation, favors engorgement of the pelvic vessels. This naturally leads to uterine congestion and excessive menstruation. In addition, disorders of the arterial system associated with high tension or endarteritis may be a factor.

3 **Hypothyroidism**.—The menorrhagia often noted in myxedema and minor degrees of thyroid hypofunction illustrates the degree to which the ovary is dependent upon normal thyroid function.

Local Causes—1 **Inflammation**.—Inflammation, either acute, subacute or chronic, of the cervix, uterine body, fallopian tubes, ovaries, pelvic peritoneum, or pelvic cellular tissue, is nearly always associated with excessive menstrual discharge.

2 **Ulcerations**.—Ulcerations of the cervix or vagina, whether simple, tuberculous, syphilitic or malignant, provoke excessive menstrual discharge. In this category may be listed senile vaginitis, ill-fitting pessary and prolapse of the uterus.

3 **Neoplasms**.—Tumors, both benign and malignant, involving the cervix, endometrium, myometrium, or serous covering of the uterus may cause profuse and prolonged menstruation. Myomas of the inter-

stitial type may be influential, but not to the same extent as those of the submucous variety. Subserous tumors, if small, do not cause bleeding, but if of large size, owing to pressure engorgement, abnormal hemorrhage may occur.

DYSFUNCTIONAL UTERINE BLEEDING—Bleeding of endocrine origin is termed functional bleeding. This term is a misnomer. More aptly it should be called dysfunctional uterine bleeding. An interval shorter than sixteen days or a flow lasting more than eight days is abnormal. The endocrine organs most commonly responsible for excessive menstruation are the pituitary gland and ovaries. Thyroid dysfunction may, likewise, provoke free menstrual bleeding.

Functional menorrhagia is especially common (1) with the onset of puberty and (2) in the early menopause, although it not infrequently occurs in mature women under 40 years of age.

Functional menstrual disorders result from an ovarian failure. This may be primary due to inherent ovarian disease or secondary to extra-ovarian causes such as pituitary disease or other endocrine lesions or various types of constitutional disease. The approximate degree of ovarian involvement is indicated by the endometrium.

In patients with this symptom, uterine curettage usually reveals a hyperplastic endometrium characterized by a dense vascular stromal and epithelial overgrowth. The glands are large and cystic, representing the characteristic "Swiss cheese" pattern, large dilated glands being found side by side with others small and narrow. Many of these are lined by several layers of epithelial cells and show no secretion in the lumen.

Functional bleeding is usually due to deficient activity of the anterior pituitary lobe. This deficiency results in an imbalance of the two hormones of the ovary manifested by a prolonged production of the estrogenic hormone. This is associated with an absence or deficiency of the corpus luteum hormone. The abnormal development of the unantagonized follicle due to the failure of luteinization results in follicular cysts of varying size.

In the early menopause a certain number of women exhibit a tendency to menorrhagia or metrorrhagia. After eliminating carcinoma, myoma or polyps as causative factors by performing a diagnostic curettage, a functional origin must be considered. In these patients sclerotic changes in the ovarian parenchyma and the tunica albuginea render the follicle incapable of completing its cycle or of responding to a normal or even an increased pituitary function.

Occasionally, postmenopausal uterine bleeding is encountered, due probably to a temporary reactivation of the graafian follicle. This condition must be distinguished from granulosa cell tumors of the ovary which produce similar clinical and endometrial changes.

Treatment of Functional Uterine Bleeding—In the treatment of bleeding of endocrine origin the mere removal of the hyperplastic endome-

trium does not bring about permanent cure. Unless the underlying endocrine disorder is overcome, the condition will recur

The treatment of functional uterine hemorrhage may be considered under three groups (1) pubescent bleeding, (2) maturity bleeding and (3) menopausal bleeding

1 *Pubescent Bleeding*—In pubertal bleeding the ovary is usually at fault, i.e., there is an absence of progesterin, except in the rare instances of Fröhlich's disease. One generally finds a high gonadotropin and low estrogen curve. The endometrium may be hyperplastic or atrophic. The treatment recommended for the more serious cases is as follows

- (a) The vagina should be packed through a Kelly cystoscope.
- (b) A blood transfusion.
- (c) Desiccated thyroid, $\frac{1}{2}$ grain three times daily
- (d) Insulin hypodermatically 5 to 10 units, before the morning and evening meal, improves health and has a definite ovarian influence.
- (e) Progesterone, 10 mg injected twice weekly. Occasionally this may precipitate bleeding
- (f) Testosterone. This affords, as a rule, better results than other endocrine therapy. In the first week 150 mg may be required followed by 50 mg per week for several months, gradually reducing the dosage.
- (g) Low dosage irradiation of the ovaries (50 to 80 roentgen units per treatment) may be used as an adjunct in certain cases.

2 *Maturity Bleeding*—During the childbearing period the administration of gonadotropic anterior pituitary-like hormone acts, it is claimed, as a specific. This hormone has a tendency to complete luteinization and is, therefore, a logical form of treatment for women under 40. One thousand rat units are given hypodermically daily until the bleeding subsides and every other day for two months thereafter. In obstinate cases, low dosage irradiation of the pituitary gland and ovaries has proved of value. Snake venom has been recommended and favorable results have been reported following the administration of this material.

Biskind presents evidence that menorrhagia and premenstrual tension related to an excess of estrogen, are caused by failure of the liver to inactivate estrogen because of deficiency of the vitamin B complex. Administration of B complex orally in daily doses of thiamine 9 mg., riboflavin 9 mg., nicotinamide 75 mg., led to prompt improvement of these conditions

3 *Menopausal Bleeding*—Patients approaching the menopause often show a compensatory excess of the gonadotropic hormone of the anterior hypophysis. The administration of gonadotropic hormone is, therefore, of no value. The injection of 300 mg of testosterone propionate over a period of one month, it is claimed, is of value. Radium is the treatment of choice.

Radium in Functional Bleeding—If abnormal menstrual bleeding fails to respond to the simple measure outlined, radium may be used

but this should be employed only after ordinary means have failed. In the early menstrual life of women, only small doses of radium should be administered, and then, too, with extreme caution on account of the probability of inducing sterility or establishing a premature menopause. Temporary and even permanent amenorrhea may follow a 200 or 300 mg.-hr. dose. After the menopause, however, 600 to 1500 milligram-hours may be administered with impunity.

ENDOCRINE FACTORS CONCERNED IN ABNORMAL AND SUBNORMAL GENITAL DEVELOPMENT

CHARLES WILLIAM DUNN, M.D., F.A.C.P.*

THE postnatal development of the female genital tract, its accessory organs and the female secondary characteristics are directly controlled by hormonal factors contained in the anterior-pituitary-gonadal axis. The anterior pituitary gonadotropic factor activates the ovary to development and at the same time increases its hormonal function during the prepuberty years. This is a gradual and progressive process during the first decade of life and while not biologically demonstrable in early childhood it is physically and psychologically evident. Not until the tenth year of life is definite evidence present that the anterior pituitary-gonadal mechanism exists. The first objective evidence that this axis is operating is obtained by the demonstration of the anterior pituitary gonadotropic factor in the urine. A few months after this event an increase in the titer of estrogen is found. A few years later as puberty is approached the anterior pituitary-gonadal axis begins to exhibit its normal cyclic phases of excretion, characterized by a rise in anterior pituitary excretion to a peak point and a more gradual rise in estrogen secretion. These cycles continue until the estrogen excretion reaches a peak of premenstrual titer while at the same time the anterior pituitary gonadotropic secretion has fallen to its low cyclic point. These cycles are regularly maintained until the menarche occurs and thereafter normally maintain themselves during the reproductive period of life. At some variable period of time, probably a few years after the menarche, the reproductive human female structure the ovary becomes part of this lunar cycle. This, briefly, represents the primary normal functional role of the anterior pituitary-gonadal axis and its hormonal sphere of activity.

The majority of young females possess a normally functioning anterior pituitary-gonadal axis and therefore one observes during childhood a progression of developmental events, which are constituted as feminine physique and psyche, feminine attributes, internal and external feminine genital organs and feminine secondary sex characteristics. However, the pattern of sex is genetically laid down during fertilization of the ova and is established during early embryonic development and fetal maturation.

Anomalies of development occur in the female genital tract which are construed as being primarily of genetic origin, with possibly early

Assistant Professor of Medicine Graduate School of A* I
of Pennsylvania, Philadelphia.

hormonic influences as a supplemental cause. It must be remembered that basically the body develops from two corresponding embryonic segments and that the primary and secondary genital organs and structures develop from the mullerian and wolffian ducts which in turn have a common segmental embryonic origin. It is the influence of the primary genetic factor and the hormonal dominance activating the embryonic structures which determine the sexual normal or abnormal pattern. It is when there is some alteration from normal influences that we observe developmental anomalies, the most typical of which is hermaphroditism or pseudohermaphroditism.

HERMAPHRODITISM AND PSEUDOHERMAPHRODITISM

True hermaphroditism is rare and is characterized by an internal and external genital tract which is made up one-half of masculine structures and the other half of feminine structures. Externally the genital area shows a moderately developed penis and a testis and a rudimentary vagina. A pseudo-hypospadias exists in most instances, and also present are well-developed breasts. The hirsutic pattern may be heterosexual. The physical features are predominately feminine, however, the female appearing to respond psychologically to the dominance of the genital pattern. In such cases one cannot be guided exclusively by the hormonal assay in arriving at the final disposition of the case. It is a far safer procedure to request exploratory laparotomy, investigate the pelvic structures and be guided by the dominance of the internal anatomical development, provided the parent in the case of minors is fully appraised of the ultimate physiologic importance of Nature's own biologic reactions. In adults the problem is more complex because certain of these individuals have economically established themselves in one sex or the other. For example, a structurally developed adult female pseudohermaphrodite had established herself in a male occupation. She sacrificed her genital internal organs and proceeded in life as a male.

Such unfortunate states should be corrected as was done in the case of T.S., early in life, and who until age four years, was raised as a female. During hospitalization for a tonsillectomy and adenoidectomy, anomalies of the genital external tract were observed. These were an enlarged clitoris, abnormally large labia and imperforate vagina. Examination and closer inspection revealed that the labia had rudimentary rugae, the enlarged clitoris was an underdeveloped penis, the normally placed urethral opening for the female was actually a hypospadias, the imperforate vagina was actually a cleft type, anomalous scrotal development and careful palpation showed very small testes high in the inguinal canal.

In this instance we were dealing with a male in spite of the fact that the abnormal external genital structures resembled those of the female. A picture of the opposite type was obtained in the case of B.L., to be described presently, who had a greatly hypertrophied (male size) clitoris.

HYPERTROPHY OF THE CLITORIS

The human embryo develops from bilateral segments which are similar in structure. The genital organs and urogenital tract develop from the same segmental site and from two structures, the wolffian and müllerian ducts. Under genetic and hormonal influences the müllerian ducts develop into the female genital and gonadal structures and from the wolffian structure develop corresponding male organs. However, in the female, certain wolffian structures, from which the male generative and genital organs develop, do not completely fail to differentiate and possess masculine features. This type of tissue is found principally in the clitoris but may be present also in the ovary in the form of rests or inclusions of medullary cords or tubules and the latter remain as potentially androgenic-producing tissues, whereas the clitoris will react and develop under androgenic stimulation. Thus in the female genital tract we have one structure which is responsive to androgenic stimulation and sometimes in the ovary one structure which can develop into tissue which is capable of producing androgens. The clitoris hypertrophies because it is sensitive to stimulation by the androgens. The abnormal quantities of androgens which stimulate the clitoris to develop to abnormal sizes and often produce an erectile response arise from an arrhenoblastoma or an adrenal rest tumor of the ovary, from a hyperfunctional adrenal cortex or from hermaphroditic organs. The degree of clitoral hypertrophy and its progression depends upon the androgenic activity of the tissue at fault. The hypertrophy of the clitoris represents only a part of the total endocrinous picture. Other features are advancement of general and secondary hair growth, acne, advanced muscular development, deepening of the voice pitch, and a general physical tendency towards masculine attributes.

Fortunately, a hypertrophied clitoris which has developed because of the presence of abnormal quantities of androgens will return to its normal proportions when the androgens are restored to normal levels. The treatment of this hypertrophy is removal of the endocrine element which generates it—the ovarian arrhenoblastoma or adrenal rest or the adrenal cortical tumor, benign or malignant. The presence of the former is best determined by exploratory operation in young female children and of the latter by perirenal air injection. Occasionally, however, all possible measures fail to reveal the source of the androgens and quite properly the surgeon will not sacrifice either gland in the hope that he will remove the cause of the condition.

Patient B.L.'s clitoris was enlarged to the size of the penis of a 16 year old male and erected frequently day and night. Her physical build was strongly masculine, she was staturally overdeveloped, the voice was of deep pitch, hirsuties of the male type were present. Exploratory laparotomy revealed normal appearing ovaries and internal genitals and palpation of the adrenals showed them to be apparently normal. The exploratory laparotomy was completed and resection

of the clitoris was performed. Two years later the general body masculinization was still in progress, and was evidenced by increasing hypertrichosis, abnormal gain in height and muscular development, distinct masculine osseous build, abnormally deep pitched and raspy voice and regrowth of the clitoris to 2 inches in length and $\frac{7}{8}$ inches in diameter. Erections of the clitoris occurred day and night and were extremely annoying. The right adrenal gland was found at exploration to be normal.

The referring gynecologist considered further surgery inadvisable and the patient was referred for medical therapy. During the past three years she has received practically continuously 0.5 to 1 mg of stilbestrol daily with beneficial results. The clitoris has diminished 50 per cent in size, erections are inhibited as long as therapy is maintained, the voice pitch is gradually approaching feminine qualities, the hypertrichosis has been controlled and the general evolution of growth and psyche has distinct feminine trends. Vaginal discharge and breast development are not prominent. Intermittent therapy results in a return of clitoral erections and cessation of vaginal discharge and breast development.

Precocious puberty sometimes occurs in males with pineal tumors, but it has not been observed in females from the same cause. It is possible that intracranial lesions exerting pressure or invading the hypothalamic centers about the infundibulum may produce a precocious pubertal state. One of our patients developed precocious puberty, advanced osseous development and impaired vision at the age of five years. X-ray therapy produced satisfactory improvement. Ten years later the visual defect reappeared and progressed to the point that intracranial surgery was performed and a large pituitary cyst was evacuated. This patient has subsequently failed to develop either normal primary or secondary sexual characteristics. Presumptively her early precociousness resulted from the embryonic type of secreting cells contained in the Rathke pouch cyst and their subsequent degeneration, possibly as the result of the x-ray. Their subsequent replacement by cystic fluid produced a cure of the precociousness but also eventuated in complete sexual retardation.

PRECOCIOUS SEXUAL HAIR DEVELOPMENT

The appearance of hair in the pubic and vulvar regions and later the axilla is considered as an event indicating the approach of puberty. The premature appearance of hair in the female genital region is therefore of great concern to the parents. In one case the child was born at term to a 20-year-old mother. At birth the child was normal. At the age of 3 years the parents noticed the appearance of hair in the pubic and vulvar regions. The hair was dark and coarse. The child was otherwise normal. At the age of 4 years the hair had increased and the axillary hair also was present. The parents feared that precocious sexual development would result. The child was otherwise normal. At the age of 5 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 6 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 7 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 8 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 9 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 10 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 11 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 12 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 13 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 14 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 15 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 16 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 17 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 18 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 19 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 20 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 21 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 22 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 23 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 24 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 25 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 26 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 27 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 28 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 29 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 30 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 31 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 32 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 33 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 34 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 35 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 36 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 37 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 38 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 39 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 40 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 41 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 42 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 43 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 44 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 45 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 46 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 47 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 48 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 49 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 50 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 51 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 52 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 53 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 54 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 55 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 56 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 57 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 58 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 59 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 60 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 61 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 62 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 63 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 64 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 65 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 66 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 67 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 68 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 69 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 70 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 71 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 72 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 73 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 74 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 75 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 76 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 77 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 78 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 79 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 80 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 81 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 82 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 83 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 84 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 85 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 86 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 87 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 88 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 89 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 90 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 91 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 92 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 93 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 94 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 95 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 96 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 97 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 98 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 99 years the hair had increased and the axillary hair also was present. The child was otherwise normal. At the age of 100 years the hair had increased and the axillary hair also was present. The child was otherwise normal.

Thus we had a three year history of prematurity in hair growth, which began in a nongenital area. I have observed a number of young female children with markedly excessive and generalized body and extremity hair growth. My observations of these individuals together with a large group of adolescent and adult females with hypertrichosis has led me to classify the cases in four etiological groups (1) Cushing syndrome including arrhenoblastoma of the ovary, (2) adrenal cortical hyperplasia or adenoma, (3) the hereditary type and (4) increased sensitivity of the hair follicle end organ to androgenic stimulation. The case of M.N. belongs primarily in the last group but because of the maternal tendency to mild and localized abnormal hair growth an hereditary factor might also be considered as present. The usual progression of events in the case of M.N. would be that in a year or two excessive hair growth will be observed in the lateral facial regions, the outer portions of the upper lip, the submental regions and eventually on the body in general. If good ovarian function develops and estrogens are normal or above normal in quantity the likelihood is that the hypertrichotic tendency will be controlled. If the hereditary factor is prominent or there develops an intercurrent adrenal cortical hyperplasia, possibly due to failure of the adrenal cortex to involute properly from the enlarged state of infancy, the likelihood of good ovarian function diminishes. The ovarian failure is incidental to the deleterious influence of the adrenal cortical hormone on the ovary. Another type of deleterious reaction on the ovary follows mumps. The importance of the latter is not generally recognized.

RETARDED DEVELOPMENTAL STATES

The anterior pituitary gonadotropic factor is the motor of the ovary. The primary and secondary female sex organs normally are in an abated state of development during the first decade of life. A minor degree of growth occurs in the primary internal and external genital structure during this period but this growth is chiefly in the structural tissues of these organs and is essentially a somatic growth effect and is not accompanied by an increase in functional capacity. This growth is nevertheless extremely important to the organ's subsequent functional capacity and is also effected by endocrine factors, namely, thyroid hormone and anterior pituitary growth factor operating as general stimulators of somatic and cellular development. If a thyroid deficiency exists during the first decade of body development, when the female sex organs are in an essentially functional dormant state, one is likely to have a deficit in early development and a delay in functional development when the second decade is entered. The anterior pituitary growth factor might be said to exert itself in the development and maturity of the cell mass whereas the thyroid is especially active in giving vitality and integrity to body cell mass. The early postnatal growth of tissues in the genital structures is

part of the general body growth and is produced by the combined influences of the anterior pituitary growth hormone and thyroid hormone. The loss of this synergistic hormonal effect is well demonstrated in the cretin. Thyroid hormone is very essential to the normal development of all cells and particularly those cellular changes which are concerned with the higher functional capacity, the reproductive cells and tissues are definitely in this classification. Thus many functional disorders of the internal genital organs are the result of early or later acquired thyroid or anterior pituitary deficiency and in the adult range from sterility to metrorrhagia. Therefore, in subnormal developments of the genital tract and retarded genital functional development we must investigate for anterior pituitary and thyroid deficiencies as well as a deficiency in the anterior pituitary-gonadal axis. The general features of this type of disorder are compositely represented in pituitary infantilism and often persists to adult life producing a major psychological and sociological problem.

D. H., an unmarried woman 24 years of age, typifies this clinical problem. Since the age of 12 years she had sought treatment for her statural and sexual underdevelopment. She is 57 inches tall, weighs 113 pounds, and the relationship of the lower measurement, span and height are proportionate. The wrist formation is atypically achondroplastic. Mentally she is depressed, chiefly because of the primary amenorrhea, infantile genitalia, very deficient pubic and axillary hair and absence of breast development. The thyroid was small and doughy soft in texture such as is found in the secondary type of hypothyroidism.

In general a therapeutic regimen for this patient appeared to be futile, nevertheless a therapeutic program was instituted to stimulate breast development and general tissue response. The therapy consisted in the administration of estynyl (Schering) 0.05 mg. nightly and the twice daily administration of a capsule containing 1 grain of anterior pituitary, $\frac{1}{8}$ grain of thyroid, U.S.P., and 2 grains of calcium glycerophosphate. In one month a mass about the size of a half walnut was felt beneath both nipples. The estynyl was reduced to every third night. In two months the breast tissue had developed to the size of half a small lemon, uterine bleeding first appeared at this time and persisted for thirty-six hours. One month later on June 8, 1945, a normal five-day menstrual period occurred and the breasts were the size of half a medium orange. The psychological change in this patient is solely due to her breast development and the appearance of the (therapeutic) menstrual flow.

The role of the adrenal cortex, pineal and thymus glands in genital development is not too clearly defined. We do know that hyperfunctional adrenal cortical states do have a depressant effect upon ovarian development and function. The ovaries in this disorder show diminished size and atretic follicles and because of diminished estrogen production, the breasts and the uterus are small.

VIRGINAL GYNECOMASTIA DUE TO INCREASED SENSITIVITY OF END ORGAN TO HORMONIC STIMULATION

Recently another factor has entered the field of discussion of growth development—the factor of the sensitivity of the tissue end organ to

the hormonal stimulator We have shown that the receptiveness of the end organ to hormonal stimulation occurs in an increased, diminished and in normal states The following case illustrates one type of altered end organ response to hormonal stimulation which can occur

S D., a female child, aged $5\frac{1}{2}$ years, experienced development of the right breast which began one year ago and is now the size of the early pubertal state. The left mammary region is normal for her age. Excessive statural growth is present, her height being 53.5 inches with proportions of trunk, lower measurement and span approximating that of a normal 10 year old child Axillary and pubic hair are present, together with an excessive generalized body growth of hair which corresponds in length texture and quality to that present in the axillary and pubic regions. The mental and psychological development is normal

Fig 179.—Virginal gynecomastia in infant (P M) eighteen months of age, onset at age one year

In my opinion this unilateral virginal gynecomastia represents an instance of increased sensitivity of the end organ of the breast parenchyma to estrogenic stimulation. Were excessive amounts of estrogen present one should observe bilateral virginal gynecomastia, epithelial tissue response of the uterine endometrium and the vaginal mucosa, and general advancement of feminization, all of which are absent. The normal responses of the patient are present in her mental and psychological age, the absence of uterine and vaginal response, the normal stage of development of the left mammary area and the general absence of precociousness The abnormalities, exhibited as an increased

sensitivity of the end organ to hormonal stimulation, are, unilateral virginal gynecomastia, excessive statural development and incipient hypertrichosis

Virginal Gynecomastia in a Female Infant Aged 18 Months—Premature development of the breast may occur as early as one year. It may be present as a unilateral or bilateral abnormality but it occurs more frequently as a bilateral state.

In P. M., a female infant aged 18 months, breast development was first observed at the age of 1 year. The breast tissue developed rapidly in both mammary regions and at times appeared to cause the infant discomfort (Fig. 179). During the past few months no increase in size of the breast has been noted. The birth weight was 8 pounds 2 ounces, the height 26 inches. First dentition occurred at 4½ months and the infant walked at 10½ months. At present the height is 33 inches, lower measurement 14½ inches. Sixteen teeth are present. The breasts are 2½ inches in diameter and 1½ inches deep. The breast parenchyma is 1½ by ¾ inches. The nipple and areola are developed. The breasts appear to be sensitive. The external genitalia are of normal size for age. A vaginal discharge has been observed.

While I believe that in most instances, whether it occurs in the female or the male, gynecomastia is a condition of increased sensitivity of the end organ of the breast cell to estrogenic stimulation and is not amenable to *rational* endocrine therapy which considers the body tissues as a complete functional unit, this disorder should not be dismissed as such until granulosa cell tumors of the ovary are excluded by hormonal assay and complete physical and clinical investigation. Besides producing premature breast development, granulosa cell tumors and luteoma also produce premature feminization and uterine bleeding because such tumors produce excessive and demonstrable amounts of estrogen (estradiol).

HYPERTROPHY OF THE BREAST

This condition is similar to virginal gynecomastia and may be unilateral or bilateral and may or may not be associated with signs of painful engorgement preceding the onset of the menarche or premenstrual changes. For the painful engorgement I am opposed to the use of male hormone in young females. A more practical and harmless treatment is to stimulate urinary excretion and deplete the system of the estrogen by the use of a saline diuretic and fruit juices. A special brassiere or one that uplifts the breasts, particularly on the axillary side, should be worn.

Plastic surgery is the only means of correcting unilateral or bilateral hypertrophy of the breast if the overdevelopment of the breasts is producing physical discomfort or psychologic reactions. However, before this is definitely decided upon it is well to remind the patient that their present size, which she feels she cannot tolerate, may be an asset during later years when breast atrophy normally occurs. This

compensating thought will frequently dampen a patient's desire for plastic surgery

APLASIA AND HYPOPLASIA OF THE BREAST

Many young females apparently mature normally—later adult history proves their fertility—and yet their breasts never have developed or are markedly hypoplastic. I believe that the aplasia and hypoplasia present in these cases represent an opposite state to that which is observed in virginal gynecomastia, namely, diminished end organ sensitivity to estrogenic stimulation. I have proved this conception to my own satisfaction by showing after local inunction of estrogenic ointment and oral and hypodermic administration of estrogen have failed to develop the breast, that the injection of 2.5 to 5 mg of estradiol dipropionate directly into the dense tissue under the nipple will develop it. Not until the estrogen in concentrated strength is brought directly into contact with the breast cells do they respond to stimulation. Unfortunately many such cases require protracted periods of these treatments to obtain reasonably satisfactory results but there are other cases which appear to progress satisfactorily once the breast cells are adequately activated. The oral administration of estinyl appears to be the most active stimulator of the breast tissues when aplasia and hypoplasia of the breast are present.

SUMMARY

While the anterior pituitary gonadal axis and its hormones are the chief hormonal factors concerned in feminine genital development, other hormones either act as supplements or independently on the primary and secondary genital structures and the sex characteristics of the female. During the periods of development to puberty the thyroid particularly and possibly the anterior pituitary growth hormone supplement the effects of estrogen on genital structures, and on the development of the feminine physique and psyche.

The treatment of abnormalities of female genital organs depends upon the type of abnormality present. Hormone-producing tumors should be treated surgically. Replacement endocrine therapy is applicable only in deficiency states. Inhibitive therapy such as the administration of estrogens to combat androgenic excess, can be utilized in a limited group of cases under the circumstances described. Abnormalities in the tissue end organ response to hormonal stimulation require special therapeutic management.

USES AND ABUSES OF ENDOCRINE THERAPY

JACOB HOFFMAN, M D *

ENDOCRINOLOGIC research continues to increase our knowledge of gonadal and reproductive physiology and add to the number of diagnostic technics and potent hormonal preparations useful in gynecologic disorders. The physiologic and diagnostic aspects of gynecic endocrinology still remain vague and confusing to many practitioners, but all have found within their grasp the numerous biologically potent sex hormones now available for clinical use. It is easy to understand their eagerness to employ these substances in the treatment of amenorrhea, uterine bleeding, dysmenorrhea, habitual abortion, sterility and other gynecologic disorders which have so long baffled the clinician. Unfortunately, when they turn to the medical literature for guidance in the application of these hormones, they are soon bewildered by the widely divergent views expressed by apparently equally competent investigators. Some maintain that organotherapy deserves a prominent place in the treatment of functional gynecologic disorders, while others insist that its sphere of usefulness is limited and its efficacy questionable.

While many of the more optimistic reports are undoubtedly in good faith, they cannot be accepted at face value either because of their failure to use controls, or to take into account the fact that a large percentage of such disorders, particularly in younger women, are subject to spontaneous correction or respond readily to general hygienic measures and psychic suggestion. The psychotherapeutic effect of organotherapy, especially where the hypodermic route is used, should be borne in mind when evaluating the results of treatment. In following the evolution of organotherapy, one is struck by the fact that brilliant results have been reported at one time or another in virtually all disorders affecting the sexual sphere, with all the sex hormones, given singly or in combination, whether in relatively inert or potent form, and whether given in large or ridiculously small doses. Investigators reporting favorable results have often been led by their subsequent experience to modify or reverse their original judgment. Unfortunately, this may either fail to come to the practitioner's attention or be obscured by persistent allusions to the original favorable reports, contained in the pharmaceutical literature which reaches him at frequent intervals.

Some general practitioners and even some gynecologists, acting in good faith, continue to employ organotherapy after doubt has been cast on its efficacy, because they are loathe to relinquish one therapeutic weapon before another is offered to take its place. Their "give it anyhow" attitude is justifiable only if the treatment is certain to be harmless, and the thought that something concrete is being done is

* Associate in Gynecology, Jefferson Medical College, Pathologist in Gynecology, Jefferson Medical College Hospital, Philadelphia

likely to have a favorable psychological effect on the patient commensurate with the expense incurred. Unfortunately, sex hormone therapy used promiscuously and without a rational basis may often do harm.

For example, the estrogens, though stimulative in their effect on the müllerian derivatives, may have a depressive effect on the anterior pituitary and ovary, defeating the ultimate aim of treatment. Since these substances exert multiple effects in the organism, the clinician who aims at one target may find himself striking others which he had no intention of hitting. Thus, estrogens used for gonorrheal vaginitis in young girls may occasionally cause cystic mastitis.¹ If administered for the control of vasomotor symptoms in post-menopausal women, they may induce uterine bleeding, necessitating curettage and the immediate application of radium until malignancy can be excluded.^{2, 3} This has been a fairly common experience since this form of therapy became popular. The carcinogenic action of the estrogens, of which there is suggestive though not conclusive evidence in the human being,⁴ should be borne in mind, particularly where there is a familial history of genital or mammary cancer.

The use of androgenic substances in the female is obviously nonphysiologic. Aside from their possible masculinizing effect, their suppressive action on the ovary in the susceptible case, may prove more lasting than was originally intended. The gonadotropes now available for clinical use, whether of anterior pituitary equine or chorionic origin, are likely to be of little value and, under some circumstances, may even do harm. In the light of the clinical evidence at hand, it is doubtful whether they can initiate normal cyclic changes, including follicular maturation, ovulation and corpus luteum formation, in the hypofunctioning human ovary. Chorionic gonadotropin from human pregnancy urine may even have a depressive effect.⁵ According to Harman,⁶ it acts as a powerful disrupting agent. A combination of anterior pituitary or equine gonadotropin and chorionic gonadotropin, given either simultaneously or in succession, may cause pathologic enlargement of human ovaries with formation of numerous cystic follicles or lutein cysts.^{7, 8} While it is claimed that these alterations are transient, we cannot exclude the possibility that the application of forces capable of causing such complete disruption may do lasting damage to the sensitive ovary.

Before resorting to any form of sex hormone therapy, *it is of the utmost importance to eliminate organic disease*. I have often encountered women harboring organic lesions who were previously subjected to prolonged hormone treatment for menopausal bleeding without a preliminary diagnostic curettage and, in some instances, without pelvic examination. Where no organic cause is demonstrable, endocrine therapy should be withheld pending proof that an actual hormonal deficiency exists. The task of establishing a deficiency is not a simple one, even in the hands of the experienced observer with all known diagnostic aids at his disposal. The tests designed for measuring the sex hormone content of the blood and urine provide only limited information, of which the interpretation is not always clear. Hormone titers show wide variations between different individuals and at different times in the same individual. Moreover, variations in technic between one laboratory and another have made it difficult to establish norms or to decide what constitutes a significant deviation.

from normal. The large majority of cases encountered in the gynecologic clinic fail to show deviations sufficiently striking to be significant or conclusive. Where a marked deviation is encountered, its interpretation may present difficulties, due to our incomplete understanding of the factors controlling the level of the sex hormones in the body fluids. The rates of production, utilization, conversion or destruction of the hormones are only a few of the variables which may affect the results.

In my experience and that of others,⁹ the most reliable and significant information is provided by histologic examination of endometrial curettings. This procedure will disclose organic lesions of the uterine cavity and in addition may provide a clue to the functional status of the ovary and its governing gland, the anterior pituitary. A thorough physical examination in the nude, with particular attention to the developmental status of the genitalia and secondary sex characters as well as the presence of endocrine stigmata, may also yield valuable information.

The hormones now on the market for the treatment of functional gynecologic disorders include the gonadotropins derived from anterior pituitary gland tissue, human pregnancy urine (chorionic gonadotropin) and serum of pregnant mares (equine gonadotropin), natural and synthetic estrogens, progesterone and pregnenolone, and natural and synthetic androgens. Space permits only a brief discussion of the disorders for which these substances have been recommended, the theories advanced to justify their use, and the possible beneficial and harmful consequences of their use.

FUNCTIONAL UTERINE BLEEDING

The sex hormones are widely used for the control or cure of functional uterine bleeding, particularly that associated with endometrial hyperplasia. Progesterone¹⁰ and the orally active progestational substance, pregnenolone,¹¹ have been advocated on the assumption that they will override the effect of the endogenous estrogens on the uterine mucosa and thus prevent excessive mucosal proliferation and bleeding. Some believe these substances inhibit the myometrial contractions and thus reduce the rate of blood flow to the endometrium. Evaluation of their efficacy in uterine bleeding is difficult because of the frequent tendency to spontaneous coagulation and the possible curative effect of other measures. Endometrial curettage, often performed on diagnostic purposes but bound not to mislead, is not an ideal method of evaluating the effect of these hormones. It is true that the administration of androgens, especially testosterone or with progesterone, is advocated by some workers who attribute its apparent beneficial effect to its ability to alter the functional capacity of the endometrial blood vessels. In their opinion, there would seem to be no rational basis for the use of this hormone in a condition which is

supplied endogenously in adequate or excessive amounts Hartman,⁶ in a recent communication, expresses a similar view.

Androgen therapy¹⁴ for the control of excessive uterine bleeding has recently become popular. Its anti-bleeding action has been variously explained on the basis of suppression of estrogen production indirectly by way of the anterior hypophysis, nullification of the effect of endogenous estrogens on the uterine mucosa, inhibition of myometrial contractions with consequent reduction of the blood flow to the endometrium, and conversion to progesterone which in turn prevents excessive mucosal proliferation and bleeding. This form of therapy would appear undesirable and at times hazardous, especially in younger women. Aside from the possible masculinizing effect of the androgens, their depressive action on the ovary and endometrium may interfere with the restoration of normal ovarian and menstrual function.

In view of evidence that persistent follicular activity without ovulation or corpus luteum formation is responsible for abnormal bleeding from a hyperplastic mucosa, many clinicians^{15, 16} have turned to the gonadotropins with the hope of correcting the underlying ovarian disturbance and thus restoring normal menstrual periodicity. To date, there is no convincing proof that these hormones can favorably affect the ovarian alterations and lead to normal cyclic activity. Hartman's experience with chorionic gonadotropin led him to conclude that there is no physiological basis for its use in bleeding associated with endometrial hyperplasia.⁶ He believes that the natural extracts of anterior pituitary gland tissue may eventually offer the best solution for inducing ovulation and corpus luteum formation in cystic and hypotypical human ovaries. Thus he bases on the report of Casida and his associates¹⁷ that crude bovine anterior pituitary extract, given in a single intravenous injection to sterile cows with cystic ovaries and endometrial hyperplasia, induced ovulation as shown by the fact that artificial insemination shortly after the injection resulted in pregnancy. Successful duplication of these results in the human subject has not yet been reported.

Prolactin, the lactogenic principle of the anterior pituitary gland, is the most recent addition to the list of hormonal preparations advocated for the control of abnormal uterine bleeding. Those reporting good results^{18, 20} differ as to its probable mode of action. Kupperman and his associates¹⁹ believe its luteotrophic action may account for its apparent beneficial effect. This seems unlikely in view of the fact that these observers could demonstrate no change in the morphology of the endometrium as might be expected if the hormone acted by stimulating luteal function and progesterone secretion. Their observation that prolactin had no demonstrable effect on the length of the cycle, amount of bleeding or morphology of the endometrium in normally menstruating women would also seem to argue against any positive

action of this hormone on the human ovary Goldzieher²⁰ believes it acts at least partly by suppressing a hypothetical bleeding factor which increases bleeding from the endometrial capillaries. It remains to be seen whether carefully controlled studies will establish the lactogenic hormone as a useful aid or throw it into the discard along with chorionic gonadotropin, which was also once credited with brilliant results in functional uterine bleeding.²¹

On the whole, organotherapy would seem to have only a limited sphere of usefulness in this disorder. In the adolescent, the condition is often self-limited and will eventually correct itself without treatment. In women of child-bearing age, curettage alone, repeated if necessary, is often effective.²² The gonadotropes should be avoided because of the uncertainty of their action and the danger that they may have a disrupting influence on an already disturbed ovary. Thyroid therapy is often useful, particularly where the basal metabolic rate is depressed. For bleeding during the late reproductive, menopausal and postmenopausal epochs, organotherapy is unnecessary, for radiation or surgery is the therapy of choice and may be resorted to without hesitation at this time of life. Endocrine therapy is not only an unnecessary expense, but if used without a thorough examination to exclude organic lesions, as is often the case,⁸ it may cause dangerous delay in the diagnosis and treatment of pelvic carcinoma.

AMENORRHEA

Since amenorrhea may result from any one of a number of causes, organic as well as functional, a careful investigation to determine the nature of the underlying disturbance is an essential prerequisite to effective treatment. Unfortunately, a search for the cause is too often subordinated because of the many bold claims that this or that sex hormone is all that is needed to combat the amenorrhea. This attitude is to be deplored, for systemic disease is often overlooked in the rush to apply the sex hormones.

Both the gonadal and gonadotropic hormones have been employed extensively for the treatment of primary and secondary amenorrhea. It is well established that the ovarian sex hormones, if given in adequate amounts over a period of two to three weeks, can develop the human uterine mucosa to the point where cessation of treatment will be followed by bleeding from an estrogenic or progestational type of endometrium, depending on whether estrogen alone or estrogen plus progesterone is used.²³ In some cases, as first shown by Zondek,²⁴ withdrawal bleeding may be induced by administering progesterone, either alone or with a small quantity of estrogen, on two successive days. Episodes of withdrawal bleeding can be induced at regular intervals as often as the patient's pocketbook will permit. Such treatment is contraindicated where the amenorrhea represents the effort of a depressed organism to conserve its depleted resources. Though the oc-

currence of cyclic bleeding may have a favorable psychological effect on the patient, there is little reason to expect the treatment to correct the underlying ovarian deficiency. Neither estrogen nor progesterone is capable of directly stimulating the hypofunctioning human ovary to normal cyclic function. Observations in the experimental animal and human being suggest that they may indirectly influence ovarian function by way of the anterior pituitary gland. At times, their action is stimulative, at times inhibitory, but the precise conditions under which one or the other effect may be expected have not been defined. Nor is there any evidence which would justify the assumption that the return of normal menses, sometimes seen after sex hormone therapy, is due to its regulatory effect on the anterior hypophysis and is not mere coincidence. Carefully controlled studies, designed to exclude the factor of spontaneous correction and the effect of nonendocrine measures concomitantly employed, are necessary before credence can be given to such claims.

The use of a potent gonadotrope to stimulate the hypofunctioning ovary would seem to have a rational basis and be the therapy of choice where the ovarian depression is secondary to anterior pituitary hypofunction. The available gonadotropins have been employed singly and in various combinations, but the response has thus far been inconstant and unsatisfactory.

Rydberg and Pedersen-Bjergaard⁷ employed large doses of equine gonadotropin followed by chorionic gonadotropin in primary and secondary amenorrhea. Increased excretion of estrogen followed by the appearance of pregnanediol, excretion product of progesterone, was demonstrated in one instance during the course of treatment. Its termination was followed by bleeding from a progestational type of endometrium. In another case, the treatment caused marked enlargement of the ovaries due to the formation of lutein cysts, associated with abdominal pain. Davis⁸ treated secondary amenorrhea with large doses of "Synapodin," a combination of anterior pituitary extract and chorionic gonadotropin. Some seemed to benefit but others remained unaffected or showed only temporary improvement. It is noteworthy that the best results occurred in amenorrhea associated with obesity. The return of normal periods coincided with loss of weight, which in the author's experience is often sufficient to bring about a return of normal menstrual periodicity. In some of the cases, Davis observed rapid enlargement of the ovaries due to formation of multiple follicles, associated with edema and interstitial hemorrhage. Cyst formation was also noted. The experience of these observers suggests that effective treatment for secondary ovarian hypofunction may eventually become available, but it emphasizes the dangers inherent in the use of gonadal stimulants without precise information as to dosage, timing and the probable reaction of the ovaries in a given case.

Fortunately, the limited usefulness of organotherapy in amenorrhea is not a serious matter, for many cases of amenorrhea, particularly in younger women, are subject to spontaneous correction or respond readily to nonendocrine treatment. Amenorrhea of psychic origin is often self-limited or amenable to psychotherapy.

Of interest is the observation of Whitacre and Barrera²⁵ that amenorrhea occurred in 14.8 per cent of the women of menstrual age interned at Santo Tomas in Manila. In many of the cases, the menses stopped abruptly either immediately after the first bombing of Manila or shortly after internment and too soon to be attributable to nutritional deficiency. These observers conclude that psychic shock, worry and especially fear were responsible. Hormone studies revealed a deficiency of estrogen associated with normal or possibly excessive quantities of gonadotropin. They suggest that the shock caused amenorrhea by suppressing ovarian function through the mediation of the autonomic nervous system. Most of the women had a spontaneous return of normal periods after a few months. Gonadotropin therapy was withheld because of the positive gonadotropic hormone tests. Sex hormones were not available. For want of something better, vitamin E, which happened to be on hand, was given in doses of 20 drops three times a day for ten days. Eight of ten patients so treated experienced a flow at the end of treatment. Since there is no reason to expect stimulation of the generative tract from such therapy, Whitacre and Barrera assume that the good results were mainly due to its psychotherapeutic effect.

Where the cause of the amenorrhea is a nutritional deficiency, a well-balanced, vitamin-rich diet is often effective, while amenorrhea associated with obesity often responds to reduction of weight through dietotherapy. Small doses of thyroid are a useful adjunct in the treatment, particularly where the basal metabolic rate is low. The use of any metabolic stimulant is contraindicated, however, where the low basal metabolic rate is associated with nutritional deficiency or some other constitutional depressive state, for here it apparently represents an effort of the organism to conserve its waning resources.

DYSMENORRHEA

Menstrual pain in the absence of demonstrable pathologic change has long baffled the gynecologist. An endless number of theories have been proposed and equally numerous remedies tried for its relief or cure. Recent evidence suggesting a possible endocrine basis has encouraged the wide use of organotherapy. The reported results have been inconstant and are difficult to evaluate because of the important part played by the psyche in this condition. Confusion arises from the fact that equally good results have seemed to follow opposite forms of treatment, while both good and bad effects have been described after identical therapy. Thus far, a significant advantage of endocrine therapy over general hygienic measures and psychotherapy has not been convincingly demonstrated.²⁶

Some observers employ progesterone²⁷ or pregnenolone²⁸ with the aim of inhibiting myometrial contractions and promoting the excretion of the motility-stimulating hormone, estrogen. Others oppose this form of treatment on the ground that pain is associated with a pregravid type of endometrium and can be prevented by measures calculated to prevent corpus luteum formation and conversion of the endometrium to the pregravid phase. They reason that progesterone may be expected to aggravate rather than allay menstrual pain. In their

opinion, the use of estrogen²⁹ or androgen³⁰ to suppress ovulation and thus prevent painful ovulatory bleeding has a more rational basis. Though there is a growing body of evidence that pain is usually absent during anovulatory menstruation,³¹ suppression of ovulation to relieve the dysmenorrheic patient is hardly desirable, particularly in young women. Repeated interference with normal cyclic events in the ovary is not only certain to lower the fertility index but such tampering may disturb the endocrine equilibrium and cause lasting damage. In addition, severe uterine bleeding may sometimes follow estrogen therapy,³¹ while the androgens may cause masculinization.

Some observers maintain that uterine hypoplasia is an important etiologic factor in dysmenorrhea and advocate estrogen therapy for its growth-promoting effect, wherever the two conditions coexist. The hormone is administered during the first half of the cycle in relatively small doses to avoid inhibition of ovulation. Jeffcoate, in a recent communication,³² presents evidence suggesting that this view is unfounded. He concludes that since uterine hypoplasia is not a cause of menstrual pain, estrogen therapy to develop a hypoplastic uterus cannot be expected to relieve an associated dysmenorrhea.

The equine³³ and chorionic³⁴ gonadotropes have been administered with the aim of directly inhibiting myometrial activity or stimulating luteal function and thus increasing the supply of the motility-inhibiting hormone, progesterone. The earlier enthusiastic reports have recently given way to skepticism.

It is thus apparent that little is to be gained from the use of endocrine products in the treatment of dysmenorrhea. Even where relief from pain is obtained, the price paid, in terms of danger to gonadal function and other undesirable effects, seems too high, particularly since equally good results are obtainable, without danger to the patient, through improved hygiene and psychotherapy.^{31 35 36}

STERILITY

The value of any form of therapy in sterility is difficult to estimate because the conscientious physician usually employs all the means at his command from which some benefit might reasonably be expected. The possible curative effect of tubal insufflation and endometrial curettage, routinely employed as diagnostic procedures, also tends to obscure the effect of any method of treatment. Of interest in this connection is Sharman's report³⁷ that among 257 cases of primary sterility, in which insufflation or lipiodol injection of the tubes and endometrial biopsy failed to show any barrier to pregnancy, 116 or 45 per cent subsequently became pregnant without further treatment.

Organotherapy may be resorted to for the treatment of sterility only after excluding or eradicating mechanical obstacles to union of the gametes and nonendocrine faults likely to interfere with egg production.

The estrogens have been employed with the aim of developing a hypoplastic uterus, enlarging the tubal lumen, altering the cervical secretions so as to make them more permeable to the ascending sperm, or modifying the vaginal secretions so as to provide a more favorable medium for the deposited sperm. Unfortunately, the dosage required for these effects is sufficient to inhibit ovulation, an effect which is obviously undesirable where fertility is the main objective.

Administration of a potent gonadotrope capable of inducing normal cyclic changes in the ovary would seem to be rational therapy in sterility due to deficient oogenesis, secondary to anterior pituitary hypofunction. Such a deficiency may exist not only in women with amenorrhea or irregular uterine bleeding, but also in those who have apparently normal flows at monthly intervals. The occurrence of an-ovulatory cycles in such women is now generally conceded, though estimates of their incidence vary widely. In a recent study, Sharman⁸⁷ found such cycles in 64 per cent of 358 cases of primary sterility. It is regrettable that the available gonadotropes, in their present form and with the existing limitations on our knowledge concerning their proper application, are of little value and may even do harm in such cases.

There is evidence that with proper control of dosage and timing, ovulation may be induced with gonadotropic substances in the monkey,³⁸ cow¹⁷ and other species. In the human ovary, the response to similar therapy has thus far been disappointing. Typical is the report of Wilson,³⁹ who used equine gonadotropin for sterility and at first got results which appeared most encouraging but, in the light of his subsequent experience, proved to be pure coincidence. The ability of the gonadotropes to induce ovulation in the hypofunctioning ovary has not yet been convincingly demonstrated. When brought to bear on ovaries which show some degree of function, they induce alterations which quickly pass the limits of the physiologic. For example, Davis and Hellbaum⁴⁰ found that in normally menstruating, pregnant and postpartum women an extract of sheep anterior pituitary gland tissue produced marked enlargement of the ovaries, increasing their size ten to twenty-fold. The proliferative changes thus initiated eventuated in the formation of large follicles and follicle cysts. Except for three pregnant women who appeared to have ovulated just prior to laparotomy, performed following administration of the extract, none of the subjects showed evidence of ovulation or corpus luteum formation.

Equally unphysiologic effects have been described following equine and chorionic gonadotropin given in succession,⁷ and anterior pituitary and chorionic gonadotropin administered simultaneously in the form of Synapoidin.^{8, 16} Davis⁸ observed multiplication of corpora lutea and hemorrhagic follicles with much edema and interstitial hemorrhage and occasionally formation of a single large cyst. According to this observer, these changes occur rapidly but regress slowly. In some of his cases several months passed before the ovaries returned to normal size. He points out that such tumors are liable to the general risks of complications such as hemorrhage and torsion, and call for careful supervision during treatment.

It is to be hoped that proper control of dosage and timing will eventually make it possible to avoid these undesirable effects. For the present, however, these substances should be used with caution because

of their possible disrupting influence. Reports of severe allergic reactions⁴¹ emphasize the need for care. Evidence that antigonadotropin formation may follow their protracted administration⁴² further detracts from their value as ovarian stimulants.

HABITUAL AND THREATENED ABORTION

Evidence that endocrine factors play an important role in the maintenance of gestation and its successful termination has led many clinicians to resort to organotherapy in cases of habitual and threatened abortion. Progesterone or pregnenolone is employed⁴³ because of its ability to maintain the nidatory bed and its quiescent effect on the myometrium. Both large and small doses have been tried but there is as yet no convincing proof that the results are significantly better than those with bed rest, sedation and other nonendocrine measures.⁴⁴ Some observers believe progesterone is of little value and, in large doses, may even aggravate a tendency to abortion by depressing the metabolism of intrinsic progesterone.⁴⁵ Another possible disadvantage of progesterone therapy is suggested by Murphy's⁴⁶ report of prolongation of pregnancy and excessive fetal development after progesterone administration for habitual abortion. A fair evaluation of this form of treatment must await improved methods of establishing progesterone deficiency and excluding the numerous other factors, of maternal and fetal origin, which may play a part in the etiology. Recent studies suggesting that the Rh factor may account for some cases of abortion⁴⁷ emphasize the complexity of the mechanism concerned in the maintenance of pregnancy and serve as a reminder that we should not be too hasty in tagging a case as endocrine in origin and treating it accordingly.

Estrogen has also been advocated⁴⁸ for use where hormonal tests of the body fluids reveal low titers of this hormone. In view of evidence that estrogen may have an abortifacient action under some circumstances, it should be used with caution. It must be emphasized that our understanding of the mechanism controlling the hormone levels in the blood and urine during pregnancy is still incomplete. In the present state of our knowledge, we cannot be certain that low estrogen titers denote deficient production rather than increased utilization of an adequate supply. Indeed, low estrogen titers may even conceivably signify increased conversion or destruction, representing an effort of the organism to rid itself of the hormone. So long as the interpretation of these findings remains uncertain, therapy based thereon is necessarily empirical and should our guess be wrong, more harm than good may follow.

Prolactin has been given a trial in threatened abortion,⁴⁹ but the number of cases is still too limited to permit any judgment as to its efficacy.

I have reached the conclusion that general hygienic and medical measures calculated to put the patient into the best possible physical and mental state are to be preferred. Thyroid therapy is of value where the basal metabolic rate is low or fails to show the usual rise with the advance of gestation.⁴⁹ Where abortion threatens, rest in bed, mild sedation and avoidance of coitus, purgatives and undue excitement would seem to be as effective as any other form of therapy thus far proposed.

THE CLIMACTERIC

Before attempting to pass judgment on the rationality or efficacy of any form of treatment recommended for the relief or cure of the climacteric symptom complex, it is important to bear in mind that it is an expression of a general nervous and endocrine upheaval, possibly precipitated by the decline of ovarian function. The nature, intensity and duration of the symptoms apparently depend on the severity of this upheaval and the reaction of the organism to the altered hormonal and nervous environment. This in turn depends on the previous status of each system and the extent to which it is implicated in the general regression which heralds the approaching senium. Since aging and ovarian regression are inevitable and irreversible processes, it is obvious that no form of therapy can do more than ease the patient through this critical epoch.

Sex hormones, particularly the estrogens,^{50, 51} have achieved their greatest popularity in the treatment of the vasomotor and other annoying symptoms associated with the menopause. Even those who have maintained an attitude of cautious skepticism regarding their value in menstrual and reproductive disorders, have permitted themselves to become enthusiastic concerning their use for this purpose.

The degree of the enthusiasm for estrogenic therapy in the menopause varies. Some find the estrogens effective only for the control of flushes, while others claim good results in a variety of conditions including kraurosis vulvae, arthritic pains, intestinal symptoms, hypertension, edema, hyperglycemia and glycosuria, respiratory and circulatory disturbances, dysuria and incontinence, and involutional melancholia. Since gonadal involution with consequent estrogen withdrawal is only one of many physical and psychological changes incident to the aging process, it is difficult to conceive how mere substitution of estrogen can relieve or control the complex symptomatology. In view of the large component of psychosomatic manifestations associated with this epoch, it is entirely possible that the brilliant results attributed to estrogen therapy are in large part due to its psychotherapeutic effect. It is significant that many menopausal women are relieved by reassurance, alone or with sedation,⁵² and often respond to placebos. Of interest in this connection is Frank's observation⁵³ that oral estrogen therapy, which relieved most of his patients, was without effect in a few who had convinced themselves that estrogen by this route is ineffective. If it is granted that a patient's psychic convictions can prevent her from responding to estrogen therapy, one cannot help but suspect that favorable responses, where noted, were due to the psychic conviction that the therapy would be effective.

Aside from the fact that its superiority over placebos has not been convincingly established, estrogen therapy has several disadvantages. In the woman whose menses have already ceased, the hormone may induce bleeding and compel the clinician to perform curettage in order to determine whether the hemorrhage is due to the treatment or to a lesion which has developed during its course. The danger of stimulating a latent tendency to malignancy, though not definitely proved, nevertheless merits serious consideration since there is as yet no conclusive evidence that the human being is immune to the carcinogenic activity of estrogen. Even if it is conceded that estrogen gives relief, it is at the price of postponing the complete weaning of the organism from the need for this hormone. Whether its effect is physiological, psychological or a combination of both, its continued administration may make the patient dependent on it long after she would normally require it, were treatment withheld.

Androgen therapy for the relief of menopausal symptoms is based on its supposed ability to inhibit a hyperactive anterior pituitary, which is presumably contributing to the symptoms. The danger of inducing masculinization, particularly at this time of life when a tendency to hirsutism is not uncommon, detracts from its value. As in the case of estrogen, the possibility that the relief obtained is due to the psychological rather than the physiological effect of the treatment cannot be ignored.

To the author, who has always favored general hygienic measures combined with reassurance, sedation and psychotherapy,⁵³ it is indeed gratifying to observe that the trend among careful observers, as evidenced in a recent symposium,^{52, 54, 55} is to emphasize treatment of the patient as a whole and particularly her psyche as the primary consideration, giving organotherapy a secondary and at best only a minor position in the therapeutic armamentarium.

In addition to the entities discussed above, numerous other conditions have been treated at one time or another with the sex hormones. The estrogens have been used to induce labor or stimulate it in uterine inertia, to suppress postpartum breast engorgement, and to control gonorrheal vulvovaginitis in children, senile vaginitis, kraurosis vulvae, pruritus vulvae, migraine headaches, vomiting of pregnancy, premenstrual tension, premenstrual mammary pain and chronic mastitis, frigidity, acne and hirsutism. Limitations of space prevent a detailed discussion of their value in these conditions. Briefly stated it is very limited and, in some of the entities listed, highly questionable. In none has it been conclusively shown to excel other nonendocrine measures.

DYSMENORRHEA

EDWARD H BISHOP, M D *

DYSMENORRHEA is one of the most common of all gynecologic complaints and is experienced to some degree by at least 50 per cent of all women. In spite of its frequency it still remains one of the most difficult problems to treat satisfactorily. The greatest complicating factor is that dysmenorrhea is a symptom and, unfortunately, is a symptom of not one but many varying pathologic conditions. In order to treat this symptom with any degree of success the etiology must first be determined and the problem approached in a logical manner. Too often dysmenorrhea is treated as a disease entity and too often it is treated on an empirical basis. Since this only too frequently results in failure, dysmenorrhea is often relegated to that group of discomforts which must be tolerated rather than relieved. Therefore it seems best to discuss the management by first considering the various types and causes. In this way one may develop a rational and logical consideration of the treatment.

DIAGNOSIS

Dysmenorrhea may be divided into primary and secondary types. When some demonstrable pelvic disturbance is present with dysmenorrhea as a symptom, it is classified as *secondary* dysmenorrhea. When no abnormality can be detected in the genitalia to account for the pain it is known as *primary* or *functional* dysmenorrhea. Since secondary dysmenorrhea is usually easier to diagnose and easier to treat it seems best to search for any of the possible causes for this type as the first step in the management of this problem.

The initial procedure undertaken in order to determine the etiology is a careful history and complete physical examination. In addition to the usual gynecologic history the physician should obtain a detailed history of the menstrual pain, the age at which it first occurred, the time relationship to the menstrual period, the location and radiation of the pain and recent changes in the intensity of the pain. These details often serve as valuable clues to the final diagnosis. As examples, the menstrual cramps which are primary in type usually first occur early in life, do not increase with age and occur in the early part of the menstrual period, the dysmenorrhea associated with endo-

metriosis first appears later in life, is "boring" in character, gradually increases with succeeding periods and is usually present during the entire menstrual period, while the dysmenorrhea associated with pelvic inflammatory disease first appears following infection with tubal involvement, is dull and aching in character and is felt in the lower lumbar region and lower abdomen

The history and general physical examination should be followed by a complete and thorough pelvic examination. At this time one may find evidence of any of the various pelvic abnormalities which may cause secondary dysmenorrhea. These conditions are most often endometriosis, pelvic inflammatory disease, uterine fibroids, ovarian cysts, endocervicitis, cervical and uterine polyps and, occasionally, displacements of the uterus. The diagnosis of all of these is usually easy to make and is not within the province of this discussion.

TREATMENT OF SECONDARY DYSMENORRHEA

The treatment of the various conditions responsible for secondary dysmenorrhea has been well established and need not be repeated here. The proper and adequate treatment of the primary condition will serve to eradicate the dysmenorrhea. It is well to remember that not only the obvious but any and all pelvic diseases or abnormalities should be treated since more than one factor may be the cause of the symptoms.

The one cause of secondary dysmenorrhea which is most frequently overlooked is *endocervicitis*. This diagnosis cannot be made by visual inspection alone, frequently it is necessary to insert a probe or sound into the cervical canal to or past the level of the internal os. Very often, associated with endocervicitis, one will find an obstruction of the cervical canal just below the level of the internal os, dilatation of which will relieve the dysmenorrhea. It is characteristic that when this dilatation is performed the patient will experience the same type of pain which she experiences at the time of the menses. Both the insertion of the sound and the dilatation (if it is not too painful) can be carried out safely as an office procedure if one uses sterile instruments and cleanses the vagina first with some efficient, nonirritating antiseptic solution. The 1:1000 aqueous solution of benzyl-trialkonium chloride serves this purpose very well. If such a stricture is present an office dilatation usually serves to alleviate the pain for a period varying from two to eight months, after which time it can be repeated. If desired, or if it is necessary, a more thorough dilatation can be performed under anesthesia and by using either Goodell or Hegar cervical dilators. In certain selected cases a stem pessary can be inserted and left in place through two menstrual periods, giving a more permanent relief.

By emphasizing endocervicitis as a cause of dysmenorrhea I do not wish to imply that it is the most common cause but in the swing of

the pendulum of opinion away from the mechanical theories many of these milder cases of endocervicitis with stricture are overlooked. Supplementing the dilatation of the cervical canal, treatment should be directed toward other evidences of endocervicitis such as eversion, nabothian cysts and ectropion. Cauterization or coagulation offers the best method of treatment and if done lightly and carefully one does not need fear further stricture as a result.

In a small group of cases it has been found that ureteral strictures or ureteral abnormalities may be the cause of the pain at the time of the menstrual period. In any case in which urinary symptoms are present a complete urologic investigation is indicated.

Among the laboratory procedures which are sometimes helpful are determination of the red cell count, hemoglobin and basal metabolism. Mild anemia and hypothyroidism are not prominent among the causes of secondary dysmenorrhea but may often be contributing factors.

TREATMENT OF PRIMARY DYSMENORRHEA

After one has searched for and removed the causes of secondary dysmenorrhea, there still remains the very large group of cases in which one can find no physical basis for the symptoms—the so-called primary or functional type of dysmenorrhea. Many theories have been advanced to explain the pain experienced by this group of patients, but without agreement. As yet no offered concept fits all cases and, therefore, they must be treated on a more or less empirical basis. Undoubtedly there is a large psychic element present in all of these cases which results in a marked lowering of the pain threshold. Nevertheless, these patients cannot be dismissed as “neurotic” but instead one must find some method of relieving their pain. It seems best to treat these patients in the following order:

1 **General Measures**—Good physical and mental hygiene should not be forgotten as part of our therapeutic armamentarium. Clow has reported that she was able to reduce the incidence of dysmenorrhea in a girls' school 70 per cent by having the girls take warm showers and moderate exercise during their menstrual periods, by using laxatives as indicated and by placing them on a proper, well balanced diet.

The nature of the complaint should be explained to the patient in detail. She must be made to realize that menstruation is a normal function and that normal activities should be maintained during this time. The patient who anticipates a debilitating period and prepares for it by incapacitating herself before the actual pain appears usually fulfills her anticipations.

2 **Analgesics, Antispasmodics and Heat**—The use of one of the many analgesics (acetylsalicylic acid, phenacetin, and so forth) and light sedation still remain as the most satisfactory method of treatment for the milder cases. The various antispasmodics (including the synthetic

and proprietary antispasmodics) are of dubious value and do not prove satisfactory in spite of the enthusiasm and wide publicity given them by the various commercial drug concerns. Kymographic studies, when carefully done, have failed to show that any of these have much effect in relaxing the myometrial contractions. The successes which have been reported were probably due to the psychotherapeutic effect of the administration and attention. This power of suggestion was well illustrated by a group of approximately 1000 women treated under my direction during their hours of employment. Most of these women were relieved of their menstrual pain by a mild analgesic when administered in the accustomed green tablet but when given the same medication in a white tablet only 30 per cent of the previous number experienced relief and the time loss due to dysmenorrhea was markedly increased. This increase promptly diminished when the same medication was again offered in the standard form originally used. The same results were experienced when an antispasmodic was used instead of the analgesic tablets.

Heat in any of its forms of application, whether taken internally as a hot drink or warm enema, or whether applied externally in the form of a heating pad, hot water bottle or hot bath, gives a definite sensation of relief.

Benzedrine may be included in this group of therapeutic aids. In spite of the glowing reports in the literature any benefit which it has is probably due to its ability to raise the pain threshold. The side reactions and the possibility of habit formation make it an unsatisfactory drug for continued use.

3 Endocrine Treatment—All of the many types of endocrine products have been used for the treatment of dysmenorrhea—anterior pituitary like substance, gonadotropins, estrogens, progesterone and androgens. However when endocrine studies have been made on patients with dysmenorrhea there have been no definite and repeated abnormalities in the levels of estrogens, progesterone or androgens, either deficiency or excess. Originally it was thought that progesterone would prove of value because of its relaxing effect on the myometrium but the clinical results with this product have not proved satisfactory.

The products which have proved of greatest value are the estrogens and androgens. The basis of treatment with both is that dysmenorrhea occurs only when ovulation has occurred and does not occur during an anovulatory period. Therefore, by the administration of estrogenic or androgenic substances during the early part of the menstrual cycle one may inhibit ovulation and thereby prevent pain at the time of the menstrual period. The easiest and most efficacious method of doing this is by the administration of 1 mg. of stilbestrol daily for 20 doses beginning at the onset of a menstrual period. This may be repeated during the following cycle and then followed by one or more periods of rest. The natural estrogenic products such as estradiol dipropion-

ate, estriol glucuronides, ethinyl estradiol, estrone and estradiol benzoate may be used in comparative dosages large enough to inhibit ovulation. Nevertheless stilbestrol is the drug of choice because of its comparative low cost, its effectiveness and the simplicity of its administration. The natural estrogens may be used when the toxic effects, such as gastrointestinal disturbances, prevent the use of stilbestrol.

The use of testosterone propionate is based on the same concept as the use of the estrogenic substances, namely the inhibition of the gonadotropic factor of the pituitary with the subsequent suppression of ovulation followed by an anovulatory menstrual period which is usually free of pain. This drug is not as safe as the estrogens because the therapeutic dose may approach the dose which results in masculinizing changes.

The endocrine treatment of dysmenorrhea should be undertaken with the greatest of caution. It should be employed only in selected cases and then only for short periods of time. Even though we may relieve the patient symptomatically, the cure is only temporary and as yet we do not know the late effects on the endocrine system due to the administration of these products over long periods of time. We may permanently interfere with ovulation or at the least seriously disturb the delicate endocrine balance. As long as this is a possibility it does not seem justifiable to use this method of treatment until all other forms have been exhausted.

4 **Exercise**—Adams, and more recently Billig, have proposed the thesis that dysmenorrhea may be caused by a postural defect resulting in contracted ligamentous bands of the pelvic fascia. Billig states that at the time of menstruation, due to the action of the ovarian hormones, there is a further shortening of these bands resulting in an irritation of the spinal nerves passing through and by them. He has devised some simple exercises which result in a gradual lengthening of the ligaments involved, thus freeing the nerves from their impingement. The results published by Billig and others have been quite encouraging. Recently Haman has corroborated these findings and suggested a modification and simplification of the exercises devised by Billig.

5 **Hypnosis**—Hypnosis has been used satisfactorily in a small series of cases but the field of its usefulness is limited by the necessary selection of cases and the scarcity of competent and interested psychiatrists. The results are probably due to a raising of the pain threshold by posthypnotic suggestion.

6 **Neurological Treatment**—After all of the above methods of treatment have been used there still remains a group of patients who have intractable and incapacitating pain at the time of the menses. For these, the only remaining treatment is surgical, by the performance of a resection of the superior hypogastric plexus or the presacral nerve. The results of this operation are quite satisfactory when the cases have

been carefully selected and when carried out by experienced operators. The disturbing side effects are few but certain factors militate against it. First, it carries a certain element of danger as does any abdominal operation. Second, all back pain may not be relieved. Third, in some cases there is an interference with satisfactory coitus. There is no interference with pregnancy and no change in bladder or bowel function.

CONCLUSIONS

When reviewing the literature on the treatment of dysmenorrhea one must approach the results very critically. The methods of treatment offered are many and diverse but almost every author reports from 50 to 90 per cent cure for his pet method of treatment. From a practical aspect it appears that the best methods of treatment available without endangering the patient are the milder analgesics, dilatation of the cervix and special exercises. Endocrine treatment should be used cautiously and only temporarily. Presacral sympathectomy should be reserved for those severe cases which cannot be relieved by other forms of treatment.

THE MENOPAUSE

JOHN B. MONTGOMERY, M.D., F.A.C.S.*

THE word "menopause" literally refers to cessation of the menstrual function. However, it is commonly used interchangeably with the broader term "climacteric" which denotes that transitional period in the life of woman characterized by ovarian failure, loss of the child-bearing function, cessation of the menses and regressive changes in the genitalia.

Menstruation usually ceases between the ages of 40 and 50, the average being about 47. When the menopause occurs earlier it is usually due to surgical removal of the ovaries, radiation therapy, prolonged lactation or some endocrine disturbance which is associated with a lack of ovarian function. However, in occasional instances which are often influenced by heredity, the menopause may occur spontaneously at an early age. In about 10 per cent of women menstruation does not cease until after the fiftieth year and occasionally the menopause is delayed until 55. Although normal menstruation has occasionally been noted beyond this age, such an occurrence should always be investigated by diagnostic curettage and cervical biopsy to rule out uterine malignancy or an ovarian tumor, even though the cycles are reported to be normal.

The menopause is an integral part of the process of aging, in no sense can it be regarded as a disease. However, the profound changes that occur in physiologic processes and in physical structure, together with associated emotional and nervous disturbances sometimes are responsible for annoying symptoms. On the other hand these changes, together with the freedom from menstrual distress and from fear of pregnancy at times result in marked improvement of general health, increased vitality, and a sense of well-being beyond anything that the individual has experienced during her active menstrual life.

ETIOLOGY

Endocrine Changes—The underlying cause of the menopause and its associated phenomena is failure of ovarian function with its related endocrine disturbances. This is apparently due to the normal aging of the ovary which causes it to become refractive to the gonadotropic hormone of the anterior pituitary. Failure of ovulation is probably the

From the Department of Gynecology, Jefferson Medical College, Philadelphia.

* Clinical Professor of Gynecology, Jefferson Medical College, Assistant Gynecologist, Jefferson Medical College Hospital. Assistant Attending Obstetrician, Bryn Mawr Hospital, Bryn Mawr, Pennsylvania.

first break in the endocrine cycle. This may occur abruptly or ovulation may recur at increasingly long intervals until it ceases completely. Failure of ovulation is followed by absence of the corpus luteum with its progestational influence. This defect may begin some months or even a year or more before menstruation ceases in which case the monthly bleeding is spoken of as anovulatory menstruation. Although during this phase the ovary fails to respond to the luteinizing gonadotropic hormone (prolan B) it may continue to be activated by the follicle-stimulating hormone (prolan A) so that graafian follicles continue to develop. This results in an excess of the follicular hormone (estrogen) and has been spoken of by Zondek as the polyfolliculin phase. It is during this time that abnormal bleeding is likely to occur due to fluctuations in the amount of estrogen in the blood. Finally the ovaries become incapable of responding to the pituitary influence and estrogen formation in the ovary ceases completely, although a small amount may continue to be produced by the adrenal cortex.

As the production of ovarian hormones wanes, their cyclical restraining influence on the anterior pituitary ceases and large amounts of gonadotropic hormones appear in the blood and urine. This is spoken of by Zondek as the polyprolan phase of the menopause. Whether this increase is due to a greater production of hormone by the anterior lobe of the pituitary or to failure of the ovaries to utilize it is uncertain. Its importance lies in the fact that the excess of gonadotropins is probably the prime factor in the production of many of the menopausal symptoms. This effect is probably brought about by the direct influence of the gonadotropic hormones upon other endocrine glands, notably the thyroid, adrenals and pancreas, and also by virtue of the little understood relationship of these hormones to the nervous system. The similarity between certain manifestations of the menopause (tachycardia, tremors, emotional instability, etc.) and the symptoms of hyperthyroidism is well recognized. Increased hair growth and other masculinizing changes are attributed to increased production of the male hormone (androgen) by the adrenals. The frequent occurrence of diabetes and other evidences of disturbed carbohydrate metabolism during the climacteric suggests that the pancreas also is affected by the disturbance in pituitary function. In course of time, the hormonal balance is restored spontaneously, the hyperactivity of the anterior pituitary returns to normal and the high concentration of gonadotropic hormones disappears from the blood and urine. The menopausal epoch or the climacteric has passed.

Nervous and Emotional Influences.—To women generally the menopause brings an acute awareness of advancing years. The fear of malignancy, cardiovascular mental and metabolic diseases, the lack of economic security, apprehension that menopausal changes will make them less attractive to their husbands, together with the over-reaction of the sympathetic nervous system which often results in symptoms

that are alarming to the patient, frequently creates a marked state of anxiety. This in itself may be responsible for many of the most distressing symptoms. These influences are likely to be especially damaging to the woman with marked psychoneurotic tendencies. On the other hand, although the symptoms of organic mental disease may be precipitated at the time of the menopause there is no evidence to indicate that psychoses are actually produced by failure of ovarian function.

Physical Changes—General physical changes are usually emphasized by the tendency to gain weight and particularly by the deposit of fat over the hips and girdle region. In some women these changes result in refinement of contour and increase in appearance of general good health which enhances their physical attractiveness. Regressive changes in the genital system begin after the estrogenic influence wanes. The endometrium becomes thin, the uterus becomes small and firm due to the atrophy of the myometrium and the development of fibrous tissue. The vaginal mucosa decreases in thickness (atrophic vaginitis, senile vaginitis) and the underlying supportive tissues undergo atrophic changes that sometimes result in shortening and deformity of the canal. The cervix decreases in size and at times may be hidden from view because of contraction of the vaginal vault and adhesions of the vaginal mucosa. These changes also affect the endopelvic fascia so that inherent weaknesses are exaggerated and become manifest in the development of uterine prolapse, cystocele or rectocele. The external genitalia decrease in size. The mons becomes less prominent, the small labia shrink, the pubic hair becomes sparse and the mucous membrane becomes smooth and pale. Areas of leukoplakia are common and at times atrophic changes are extreme, resulting in kraurosis vulvae. In spite of these changes the vulvar glands may continue to secrete mucus, and sexual sensations and libido may be unimpaired. The atrophic changes in the genital system may also affect the urethra and neck of the bladder resulting in urinary frequency or stress incontinence. Atrophy of the breasts may be a prominent feature although this is sometimes disguised by deposition of fat.

SYMPTOMS

It is generally conceded that the great majority of women go through the menopause without symptoms which are severe enough to interfere with their general welfare. However, with the advent of hormone therapy and the free discussion of this problem in the lay press an increasing number of women are consulting their doctors for relief of symptoms which they attribute to the menopause. In dealing with this ever-enlarging group of patients it is well to remember that symptoms which are attributed to the menopause frequently may be due to underlying organic disease. Severe menopausal symptoms will be encountered in only about 10 per cent of the patients.

Menstrual Disturbances—In a few women the menses stop abruptly, more frequently the flow becomes shorter in duration and more scant, with an increasingly prolonged interval until it finally ceases altogether. Postmenstrual staining, bleeding between periods or increased or prolonged flow which occurs so frequently at this time is never normal. It is always suggestive of malignancy and demands *immediate* investigation, including careful pelvic examination, diagnostic curettage and cervical biopsy. In no instance should such a patient be treated with hormones before such a thorough investigation is carried out. Failure to make such examinations will not infrequently result in delay in the diagnosis of malignancy. Such delay is inexcusable and may cost the life of the patient.

Circulatory Symptoms—Hot flushes are the most constant symptoms. Characterized by a sensation of heat referred to the head and neck, associated with flushing of the face, and often followed by a profuse sweat, they may last from a few seconds to several minutes. They may occur long before and persist long after the menstrual periods have ceased. In many instances they are mild and occur only when the patient is excited, while in some they occur every few minutes day and night causing much general agitation and interfering with sleep. The attacks are often accompanied by palpitation, weakness, vertigo and other vasomotor symptoms that add greatly to the patient's distress.

Elevation of the blood pressure which is common at this age is likely to be aggravated. Extreme fluctuations are frequent and many clinicians have come to regard the disturbed physiology of the menopause as an important etiologic factor in many of these patients.

Nervous Symptoms—Symptoms of nervous origin are common and may occur in great variety, especially in women of psychoneurotic tendencies. Many of these are referred to the skin. Pruritus, commonly localized in the vulvar or anal regions, may occur in any area and is generalized at times. Paresthesia, hyperesthesia and neuralgia are frequent. Headaches are often greatly exaggerated. Their origin is uncertain but in some instances they may be associated with disturbances in the pituitary. More commonly they are probably influenced by variation in the blood pressure and by the emotional tension associated with anxiety. Vertigo is very common as are insomnia, fatigue, extreme weakness and emotional instability.

Functional gastrointestinal disturbances are often greatly exaggerated and frequently necessitate thorough gastrointestinal study in order to rule out organic disease.

Arthritis.—Many clinicians now agree that a mild form of arthritis which especially affects the knees may result from menopausal disturbances. Others point out that these lesions occur most frequently in women who have gained much weight and are most likely due to trauma incident to weightbearing.

DIAGNOSIS

In dealing with the menopausal woman, a thorough survey of the patient is absolutely essential before her symptoms can be evaluated and a sound rational plan of treatment can be outlined. The problems of differential diagnosis presented by the multiplicity of symptoms are often very complex and may tax the ability of the most experienced physician. One is never justified in assuming that the symptoms are functional in origin. A complete history and a complete physical examination are essential. This should include careful examination of the breasts, bimanual examination of the pelvis, inspection of the vagina and cervix through a speculum, digital palpation and proctoscopic examination of the rectum. A blood count and urinalysis should always be made. Basal metabolism determination, electrocardiogram, evening-ground study, blood chemistry, gastrointestinal x-ray and the like should be carried out promptly if suggestive symptoms are present. Such a thorough study is really an important part of treatment. It will go far toward allaying the patient's anxiety and increasing her confidence in the opinions and advice of her doctor.

TREATMENT

In treating the menopausal patient, the physician must be ever conscious of the fact that the physiologic disturbances that produce the characteristic symptoms and physical alterations are due to the normal process of aging, and therefore cannot be prevented or reversed. It is important also to recognize the influence of the patient's nervous temperament, emotional instability, and her anxiety which is so often secondary to fears which arise from a lack of understanding of the true significance of the menopause.

Treatment should always begin with a simple, brief explanation of the phenomena underlying the menopause and of their significance. The patient should clearly understand that she is in no unusual danger of serious physical or mental illness. She should realize that rather than a portent of imminent old age, the menopause is nature's way of freeing her from the annoyances of menstruation and the hazards of pregnancy and childbirth at an age when she can live for many more years in the vigor of good health. A few minutes spent in simple explanation plus the assurance that results from a careful complete physical examination goes a long way toward alleviating the anxiety that underlies many of the menopausal symptoms. In many cases no further treatment is necessary.

General Measures—In most instances, general medical measures should be tried before instituting endocrine therapy. Measures to improve the general hygiene of living are very helpful. Many women suffer from overwork and lack of sleep. The cares of family life are heavy upon them. Faulty diet, with excesses of coffee and cigarettes, are not uncommon. Constipation, anemia and obesity are frequent

The latter although often due to overeating is not uncommonly influenced by the endocrine disturbances and in addition to dietary restriction may require special measures for its control

General sedation with phenobarbital is invaluable. In small doses three times daily and increased to 1 or $1\frac{1}{2}$ grains at bedtime, it is often the only medication that is necessary. At times one of the more rapidly acting barbiturates is preferable at night. Since sedation is often required over a prolonged period of time, bromides are not advised. Addiction to barbiturates should be guarded against by using small doses, administered in cycles which should be shortened and discontinued as soon as possible.

Endocrine Therapy—The rationale of estrogen therapy in the menopause is now accepted generally although there are some who question its value. It is pointed out that the psychoneurotic nature and the emotional instability of many patients make it difficult to evaluate the effects of treatment since much of the improvement may be due to the psychotherapeutic effect. Those who question the wisdom of estrogen therapy also emphasize many dangers, although it is admitted that most of these are theoretical and have not been proved. Hoffman states that in his experience general medical measures, reassurance, sedation and hypodermic injection of sterile saline solutions used for psychotherapeutic effect, have proved more efficacious than the estrogens or other hormonal preparations in the vast majority of cases. Both Hamblen and Novak emphasize the value of general medical measures, sedative, psychotherapy, and so forth, but point out the great value of estrogen therapy in those women who suffer from severe vasomotor symptoms. The aim in such treatment is not to overcome an estrogen deficiency indefinitely but to provide a gradual withdrawal that will enable the body to adjust itself more slowly. Endocrinologists generally agree that the best that can be expected from estrogen therapy is palliation of the most distressing symptoms.

DANGERS OF ESTROGEN THERAPY—It is well known that very large doses of estrogenic hormones will induce the development of malignant tumors in susceptible laboratory animals. Although the dose used in experimental animals is, in proportion, many times greater than the clinical dose, the possibility of influencing the development of cancer in women of menopausal age must be kept in mind. However, no definite evidence has been produced to prove that estrogen therapy can induce malignant disease in humans.

It is rather generally agreed that the prolonged use of estrogens is unphysiologic and may have harmful effects. It is very probable that the relief of vasomotor symptoms is due to depression of the production of gonadotropic hormone by the anterior pituitary. Possibly this depressing effect may involve the pituitary influence on other endocrine glands, notably the thyroid and the adrenal and thereby further interfere with normal endocrine balance. Prolonged estrogen

treatment may possibly delay the climacteric and simply "put off the evil day." Speaking of intensive estrogen therapy, Hamblen states that "the entire orderly process of sexual aging may be frustrated and unless therapy is discontinued the climacteric indefinitely may be postponed."

It is well known that estrogen therapy frequently results in uterine bleeding. Although such an occurrence usually is due to *overdosage*, it is always alarming to the patient. If the bleeding is scant and of short duration, endometrial curettage may be deferred provided careful pelvic examination reveals no abnormalities. However, if there is any recurrence of bleeding, diagnostic curettage should be done immediately and the curettings examined by a competent pathologist to rule out carcinoma.

INDICATIONS FOR ESTROGEN THERAPY—Only a small percentage (10 to 20 per cent) of menopausal women require estrogen therapy. The outstanding indication is severe vasomotor symptoms (flushes, sweats, chills) that have not responded to general medical measures. It may be tried as a therapeutic test for relief of severe headache after careful examination has ruled out organic disease and other methods of treatment have failed. Such a trial may be of value also in some patients with painful joints (knees, shoulders). Its value in vaginitis secondary to atrophic changes in the mucosa is well recognized but in this instance local application is preferable. Many clinicians believe that hypertension which originates during the climacteric may be benefited by estrogen therapy. Its use is probably justified in the management of these cases but the administration, as already pointed out, may have harmful effects.

It is questionable whether estrogens should ever be given to relieve menopausal symptoms in patients who are experiencing the irregular uterine bleeding that is so common during this period. Such bleeding is most likely to occur during the early stages of ovarian failure and is often associated with excessive estrogen levels (polyfolliculin phase). If facilities are available, determination of the output of estrogenic hormones in the urine or a study of vaginal smears will settle this point. The first of these procedures requires a laboratory and special equipment to make hormone assays. The second has recently been simplified by Shorr who has developed a technic which can be acquired readily by one trained in routine clinical laboratory procedures. It is based upon Papanicolaou's studies which showed that the estrogen deficiency brings about "a vaginal smear pattern characterized by the absence of cornified epithelial cells, and the presence of many intermediate and small round and ovoid cells which originate from the deeper layers of epithelium plus many leukocytes." Variations in the smear pattern indicate various degrees of estrogenic deficiency. Although these studies are helpful in determining the need for estrogenic therapy, they are by no means essential for the intelligent clinical management of these patients. Careful evaluation of symptoms with special consideration of

the characteristic vasomotor disturbances usually provides a reliable therapeutic index.

CONTRAINDICATIONS TO ESTROGEN THERAPY—Estrogenic therapy should not be given in the presence of carcinoma or for relief of menopausal symptoms following surgical or radiation treatment of malignant disease. In no instance should it be initiated prior to a complete pelvic examination including diagnostic curettage and cervical biopsy when irregular bleeding or abnormal vaginal discharge is present. When given to control menopausal symptoms following radiation treatment of benign hemorrhage, it is likely to produce a recurrence of the bleeding. If symptoms attributed to the menopause are not relieved after a brief trial of estrogen therapy, it should be discontinued and the patient should be reexamined for evidence of organic disease.

AVAILABLE ENDOCRINE PREPARATIONS—Estrogens—For clinical use we have available the natural estrogens which are prepared from the urine of pregnant women and pregnant mares, and synthetic estrogens which are prepared in the laboratory and are chemically unlike the natural estrogens which are alcohols of the steroid group. The important natural estrogens are *estrone*, *estriol* and *estradiol*. The latter is the most potent and is often used in the form of the benzoate or the dipropionate. The estrone and estradiol preparations are the forms most commonly used for parenteral administration. The estrone sulfate is the most potent form for oral administration. The estriol preparations are much less potent. Estrone and its derivatives are usually assayed in international units while the estradiol preparations are assayed in rat units. The rat unit is three to five times as potent as the international unit. The present tendency to develop pure hormone products whose dosage can be expressed in weight gives promise of simplifying this problem for the practitioner.

The best known synthetic estrogens are stilbestrol and its more potent derivative, *diethylstilbestrol*. This compound is not related chemically to the natural estrogens. The dose is expressed in milligrams, one milligram being equivalent to approximately 25,000 international units of estrone. Its advantage lies in its low cost and in its effectiveness when given orally. Its chief disadvantage is the frequency with which it produces nausea, vomiting and headache. Novak reports that such symptoms occurred in 20 per cent of patients in his experience. The incidence of these symptoms can be reduced by using small doses, coating the tablets and limiting the treatment to short cycles.

Androgens—Testosterone and its esters are available. The dosage is expressed in milligrams and it is most effective when given intramuscularly although ethyl testosterone is potent when given by mouth. These preparations have been used in the treatment of menopausal symptoms because they are thought to depress the hyperactive anterior pituitary. They may be given in doses of 10 to 25 mg two or three times a week for a total of 250 mg. Because of the potential harmful effects and the uncertainty of its clinical effectiveness in the relief of menopausal symptoms the use of testosterone is not recommended.

Thyroid—Administration of thyroid substance is of value in the presence of hypothyroidism. The clinical features of the case are equally as valuable as the basal metabolic rate in deciding this point. When indicated it should be given in full dose over a long period with careful medical supervision.

METHODS OF ADMINISTRATION AND DOSAGE IN ESTROGEN THERAPY—Irregular and haphazard administration of estrogens should be avoided. Sporadic doses even though large can do little good and may 1

endocrine system in a state of imbalance. The best plan is to give the hormone for a short period of time, possibly for two or three weeks, and then stop for a week and repeat. These cycles of therapy should not be continued for more than two or three months and usually should be stopped much sooner. If severe symptoms recur the treatment may be repeated for one or two cycles. The objective should be to control the symptoms promptly, using large initial doses if necessary and then reducing the dose and the length of the cycles so that the smallest amount that will relieve the symptoms is given. Under no circumstances should the administration of estrogens be continued indefinitely.

Oral administration is highly satisfactory and is the method of choice in most patients. The initial dose should be small, 0.25 mg of diethylstilbestrol or 1 mg of estrone sulfate daily. This can be varied from time to time until the optimum dose is found. The untoward effects of oral therapy can be prevented in most instances by using small doses and shortening the period of administration.

Intramuscular injection should be limited to patients in whom relatively large doses are necessary to control severe symptoms quickly. Ten thousand international units of an estrone preparation or 2000 rat units of an estradiol preparation given every four days for three to six doses are usually sufficient. Occasionally larger initial doses are necessary but these should be discontinued as soon as possible in favor of oral therapy.

The vaginal administration in the form of suppositories is indicated when there is an associated senile vaginitis. Cyclic administration of 2000 international units every third day for six doses is usually sufficient.

The subcutaneous implantation of pellets or crystals of estrogenic substances has been used very satisfactorily. It may be of distinct value in occasional instances where administration of the hormone is needed over a long period of time. Such an instance may occur following surgical castration in a young woman.

X-ray Therapy—Attempts to depress the anterior pituitary have been reported with varying results. The danger of injury to the pituitary and adjacent tissues makes its use hazardous. It is not recommended.

THE TIMING OF OVULATION BY BASAL TEMPERATURE GRAPHS

PENDLETON TOMPKINS, M.D.*

Two developments in the treatment of sterility are currently attracting attention. The first is the use of a precoital douche of Ringer's solution and glucose. MacLeod and Hotchkiss¹ found that by adding glucose to Ringer's solution the activity of sperm is prolonged. Reports on the use of this preparation, which is readily available,† are so encouraging that it should be employed often if not routinely. The patient is instructed to use the douche at the time when ovulation is anticipated and to try to retain as much of it as possible.

Some years ago it was hoped that electric methods would solve the problem of determining the time of ovulation. However, further experience with the potentiometer has thrown considerable doubt upon its reliability for this purpose. Even if it is reliable, the instrument is not generally available. Hence interest has grown in the use of graphs of the daily basal body temperature as an index to ovulation. This second important development in the study of infertility deserves full discussion.

Rhythmic variations in body temperature during the menstrual cycle were noted many years ago, were described in detail by van de Velde in 1904 and have subsequently been the subject of much comment. These fluctuations in temperature had no clinical significance until the mechanism of menstruation began to be understood. After it was known that ovulation occurs about fourteen days before menstruation it was apparent that the most striking changes in basal temperature also occurred at this time and a causal relation between the two phenomena was presumed.

Typical basal temperature graphs are shown in Figure 180, and the important characteristics are described in the accompanying legend. These three graphs are unusually fine examples of temperature curves. Such curves are not obtained unless the patient has been carefully instructed in the details of taking and recording her temperature. One can reduce the time necessary for proper instruction of the patient from fifteen or twenty minutes to five minutes by using a pair of forms prepared for the purpose. One sheet bears a detailed set of instructions and a sample of a properly executed graph, the other sheet is a blank grid devised to receive the temperature notations in graph

form Although these forms are available upon request* they are not essential Physicians may draw their own forms upon ordinary graph paper Grids with five lines to the inch are most satisfactory, and if $\frac{1}{8}$ inch is allowed horizontally for each day, and $\frac{1}{8}$ inch vertically for each $\frac{1}{8}$ degree Fahrenheit the resultant graph will be well proportioned The patient is instructed to take her temperature rectally with an ordinary clinical Fahrenheit thermometer for five minutes each morning upon awakening, before rising, drinking, eating or smoking Some investigators secure evening (bedtime) readings, and some have

Fig 180—The first graph (*top*) shows the temperature curve during a normal menstrual cycle During the first portion of the month the level is relatively low, it rises abruptly after a slight drop about fourteen days before menstruation and remains elevated until the next menstrual period Then it drops and the entire cycle is repeated The second graph was plotted by a patient with normal twenty-eight day cycles On the fifteenth postmenstrual day her husband, who had been away at an Army Camp, came home “on a twenty-four hour pass” The following day the temperature rose, the patient conceived, and the high temperature level was maintained until after the period was due If the high temperature level is maintained for more than sixteen days, in the absence of organic causes for fever, it is probable that the patient is pregnant. Hence the temperature graph is of some use in diagnosing pregnancy, and for this reason has been called “the poor man’s Friedman test.” The third graph was drawn by a woman of 43 whose menstrual intervals varied from month to month Some cycles showed the typical curve of the first graph and it was assumed that ovulation had occurred In the flat graph shown above it is presumed that ovulation did not occur In this particular case the assumption was not confirmed by endometrial biopsy This has been done in other cases

the temperature taken orally or vaginally After comparing various methods I believe that the most consistent and clear-cut graphs are obtained from morning rectal readings

If the patient exercises reasonable care, few errors will arise Since the desired information is obtained from temperature variations and not from absolute temperatures the accuracy of the thermometer is of no great importance Precision in reading the thermometer is important. Patients are instructed to note on the chart any obvious cause

for temperature variations such as respiratory infections. As a matter of fact, it is remarkable how severe infection of the nose and throat

Fig 181.—This chart is composed of temperature graphs from many patients selected to illustrate the curves in cycles of different length. It will be noted that the change from the lower to the higher temperature level, or the "temperature shift," occurs in all cases approximately fourteen days before menstruation. It does not occur "midway between periods" except in those cycles which are about twenty-eight days in duration. In determining the point at which the temperature shift begins to become apparent one may make a reckoning not from the lowest point on the graph but from the average of all the temperatures which represent the low or preovulatory phase. For example, in the graph of the thirty-one day cycle the lowest temperature occurs seventeen days before menstruation, but the first distinct rise above the postmenstrual average temperature occurs on the thirteenth day before menstruation.

can be without producing a change in the basal temperature. On the contrary, a bottle of beer or two highballs the previous evening will often produce a rise of three- or four-fifths of a degree Fahrenheit.

Unexpectedly high or low readings are always suspect, and patients are instructed to shake down the thermometer and to repeat these readings before plotting them on the graph. An intrinsic error in the record arises through the fact that menstruation beginning after the patient has gone to sleep is usually not noted until the next day and hence may be recorded as beginning on the day after it actually commenced. Such an error adds one day to the apparent interval between the temperature shift and the next menstruation.

The critical reader may inquire whether there is any proof that the temperature shift is actually associated with ovulation. If he will for the moment regard the association as hypothetical, the graphs will be presented first and the question answered later.

The great body of evidence, derived from histologic examination of the endometrium and ovary, from hormone assays, from comparison with findings in the monkey, from searches for early human ova and from clinical experience point to the fact that, in the human, ovulation precedes menstruation by a fixed interval of about fourteen days. This belief is convincingly supported by Figure 181 which is made up of temperature graphs ranked according to the length of the menstrual cycle. It will be seen that the temperature shift always occurs in the neighborhood of fourteen days before menstruation, and that the interval between the temperature shift and the preceding menses varies in proportion to the total length of the menstrual cycle.

At this point a common mistake of clinicians may be pointed out. Since the normal cycle is twenty-eight days in length, and since ovulation occurs fourteen days before menstruation, it follows that in a twenty-eight day cycle ovulation occurs midway between periods. Misdirected by this fact, physicians often advise all their patients that ovulation takes place "midway between periods" and that intercourse at such a time is most likely to be fruitful. This is untrue, as reference to the graphs of the forty-five day cycle and the fifty-three day cycle in Figure 181 make quite clear. Patients should be told that ovulation occurs about fourteen days before menstruation and should be assisted in their efforts to calculate which day of the calendar month that will be.

If the patient has intercourse near the time of the temperature shift she will have a better chance of conception than if intercourse occurs only at other times in the cycle. The second graph in Figure 180 is an example of coitus accurately, though accidentally, synchronized with the temperature shift. Conception followed. Similar graphs are seen in Figure 183. Not only does intercourse at the time of the temperature shift offer the best chance of fertilization, but I have not yet seen a record followed by pregnancy unless intercourse took place at that time. Conversely, there are many records showing imperfect synchronization with no subsequent pregnancy, in these cases better timing was often successful.

The span during which the ovum is susceptible to fertilization is believed to be short, a matter of perhaps twelve or twenty-four hours. The capacity of the sperm for fertilization is likewise thought to be brief. Since the sum of the functioning lifetimes of the ovum and the sperm is short, and since it is only in this period that fertilization can

Fig 182.—These graphs illustrate the use of temperature curves as an aid to birth control and also their use in planning conception. The patient has long cycles, and since she states that they are "never" less than thirty five days in length, she was instructed to make use of her contraceptive diaphragm and jelly from the twentieth day of the cycle until the temperature shift had occurred and not to abandon use of the diaphragm and jelly until the high temperature level had been maintained for two days. In the December-January cycle the plan necessitated contraceptive measures (whenever intercourse occurred) during a period of seven days as shown. In the January March cycle, which was fifty three days in length, the plan required use of the diaphragm during a total period of twenty-six days as shown. No contraceptives were used during the first or last portions of either cycle since conception at such times would be most improbable if not impossible. After the March menstrual period the patient decided to conceive and abandoned all use of contraceptives. The temperature shift occurred about twenty-eight days after menstruation but the graph, unfortunately, is marred by fluctuations of temperature which may have been due to a four-day attack of migraine. However the high temperature level was maintained for about five weeks which justified a diagnosis of pregnancy subsequently confirmed.

occur, the importance of determining the time of ovulation is obvious if one is treating childless couples. Much has been made of the motility of the sperm and it is implied that motility is a gauge of the sperm's ability to fertilize the ovum. Possibly, this view is correct. However I cannot forbear saying that it seems to me as reasonable to estimate the fertility of pedestrians by viewing them from the height of the Empire State Building as it is to estimate the fertility of

spermatozoa by examining them under the ordinary microscope. In both cases one sees myriads of individuals agitated by an energy which appears purposeful. They move, to be sure, but of their age, their sex, their abilities we know little. In fairness to those who believe that motility is tantamount to potency, it must be admitted that bull semen

Fig 183—Since the interval from the last menstrual period before conception to delivery averages 280 days, and since the woman with regular twenty-eight day cycles ovulates about fourteen days after menstruation, it follows that the interval from ovulation to delivery, or the period of actual gestation, is theoretically 266 days. The chart above is composed of five graphs plotted by "sterility patients" in the course of routine studies. The graphs are aligned to show the actual number of days which intervened from the last menstrual period, and from the temperature shift, to delivery. In none of these cases was labor induced, none had twins, none had babies of less than $5\frac{1}{2}$ pounds (2500 gm), none had cesarean sections. It will be seen that the interval from the first day of the menstrual period to delivery was 279, 282, 284, 284 and 294 days, and that the interval from the temperature shift to delivery was 268, 264, 265, 267 and 265 days respectively. It will also be noted that in each case coitus took place close to the time of the temperature shift. The chart may be regarded either as a demonstration of the fact that the temperature shift indicates ovulation, or, if that point be conceded, it may be regarded as confirming the theoretic duration of gestation, namely, 266 days.

is transported by veterinarians over great distances for the purpose of artificial insemination and that the same has been done with human sperm. It is said that in the case of the bat insemination occurs in the autumn and that the sperm survive until ovulation takes place the following spring. Leaving aside conjectural matters it can be said with assurance that, in the human, insemination close to the time of ovulation offers the optimum opportunity for fertilization.

It is apparent that if temperature graphs can be used to determine the time of maximum fertility they can also be used to determine the periods of minimum fertility. Details for this use of the graphs have been presented elsewhere.³ One example is shown in Figure 182. It happens that this patient used a contraceptive diaphragm during part of each of the first two cycles. Abstinence during the same period would have been no less effective.

An interesting collateral study on temperature graphs is the estimation of the date of delivery from the date of the temperature shift

Fig 184--The first graph (top) is from a patient whose last period before conception was dated September 1942. She was delivered in June, 1943 and did not menstruate thereafter. In September 1944 fifteen months after delivery, x-ray treatment was administered to provoke menstruation. A temperature shift developed and about two weeks later bleeding occurred. This was followed by regular cycles of five weeks' duration.

The second graph shows part of the record of a patient who menstruated at four to six month intervals. X ray was administered on May 1, 1944, four months after the last menstruation, in hope of improving the patient's chance of conception. On June 17 bleeding (menstruation?) occurred. This record is shown above; subsequent developments are presented in the last graph in Figure 183. About thirty days after the period of June 17 a temperature shift occurred and the patient conceived. She was delivered in April, 1945 (Details of this case have been presented elsewhere³).

tion, calculated by this graphic method, is so close to the theoretical 266 days And it is quite improbable that this degree of consistency between theory and observed fact would be maintained in a larger series of cases

Basal temperature graphs may also be used to evaluate treatment designed to produce ovulation Records of patients treated in collaboration with Dr Paul A Bishop, Director of the Department of Radiology of the Pennsylvania Hospital, are shown in Figure 184 These results were obtained by using the x-ray technic of Mazer, Baer and Greenberg ⁴

It is now proper to tabulate the reasons for believing that the temperature shift in basal body temperature graphs is a phenomenon associated with ovulation

Accepted Beliefs

- 1 Ovulation occurs about 14 days before menstruation.
- 2 Conception is most likely to occur if intercourse takes place about the time of ovulation.
- 3 The average interval between ovulation and delivery is 266 days
- 4 X-ray treatment designed to stimulate menstruation must first produce ovulation

Observations on Graphs

- 1 The temperature shift occurs about 14 days before menstruation
- 2 Conception is shown to have occurred when intercourse took place about the time of the temperature shift, conversely, pregnancy has not followed when the interval between coitus and the temperature shift has exceeded forty-eight hours
- 3 The interval between the temperature shift and delivery averages 266 days in the five cases studied
- 4 X-ray treatment for amenorrhea was followed by a temperature shift and about fourteen days later by uterine bleeding

The reason for the temperature shift is not established Two suggestions have been made The first is that the temperature is elevated by progesterone during the latter portion of the cycle In support of this contention it has been shown that the temperature of postmenopausal patients may be elevated by administration of progestin The other suggestion is that during the preovulatory phase the temperature is depressed by estrogens This is said to be analogous to the depression of temperature when stilbestrol is administered during the puerperium Not only is the cause of the temperature shift undetermined, but the precise relation of the shift to ovulation is also unknown Examination of a large number of graphs will show that the shift occurs more often after than before the fourteenth premenstrual day Further, clinical experience shows that coitus shortly before the shift is often fruitful whereas intercourse at a later day in previous cycles has failed Since the temperature shift is probably a physiologic re-

sponse to some endocrine change it seems entirely probable that it would tend to lag somewhat behind the causative factor

It should be noted that while there are reasons for believing that the temperature shift follows ovulation, there is less reason for believing that ovulation, in the sense of expulsion of the ovum, has necessarily taken place because there has been a temperature shift. Experience will soon demonstrate that many women show a steplike rise in temperature (the thirty-one day cycle in Figure 181) during some cycles, while in other cycles the same patient will show an abrupt rise in temperature (the thirty-four day cycle in Figure 181). If intercourse is properly timed in all cycles it will be found that conception is more likely to occur when the temperature rise has been sharp. It therefore seems probable that there are differences in the character of ovulation as well as in the character of the temperature curve from month to month. Indeed, our knowledge of the inconsistency of physiologic reactions makes it seem entirely unlikely that ovulation would occur in precisely the same way during every cycle, or that conception could occur at every ovulation. At the present time Dr. Edmond J. Farris of the Wistar Institute of Anatomy in Philadelphia is carrying on a fascinating investigation which supports this idea. Since his work has not been published I cannot dwell upon it, but I may say that by means of biologic reactions he has been able to predict that conception would take place in certain cycles and that it would not take place in other cycles, and that these predictions could not have been successfully made from the temperature graphs or the records of coitus which his patients have kept.

SUMMARY

The chief uses of basal body temperature graphs as an index of ovulation are (1) as an aid in advising childless women of the time of maximum fertility, (2) as a means of planning conception during a certain cycle or season, (3) as a method of avoiding pregnancy useful to those who do not use contraceptives, (4) as a method for timing artificial insemination and endometrial biopsies, (5) as an aid in securing early human ova, (6) as a help in evaluating treatment designed to produce ovulation, (7) in occasional cases as a means of predicting the date of delivery.

TOXEMIAS OF PREGNANCY

MARIO A. CASTALLO, M.D., F.A.C.S.*

THE etiological causes of the toxemias of pregnancy are not completely understood. The toxic effects of the pregnancy on the human structures, nevertheless, is well understood. The toxemias of pregnancy, from their earliest manifestations of nausea and vomiting to the last and dramatic stages of eclampsia, are thought by many to be one and the same process. The symptoms and signs differ only as to time of their occurrence, their severity and clinical manifestations.

Although there have been no startling new findings as to the causation of toxemia, nevertheless there have been some startling and definite advances made in its management and in its treatment.

Eastman and Wetheridge report that whereas the maternal mortality in toxemia of pregnancy was as high as 20 per cent, it is now down to 5 per cent. This low rate has resulted not because we know so much more about the disease but because the conservative treatment of eclampsia is started earlier and is more universal. Its fundamental principles are (1) elimination of the toxins by medical means, (2) the abolishment of drastic surgical procedures, and (3) early induction of labor if medical treatment of the patient does not show a decided improvement within a short length of time. These factors and better and earlier prenatal care have all contributed to the great saving of maternal lives in toxemia.

The greatest advances in the management of toxemia of pregnancy consist in the careful study of the blood pressure at frequent intervals, the assiduous regard for excessive gains in weight, constant watchfulness of the vascular tree by the use of the ophthalmoscope, and the institution of means to dehydrate the patient and keep her at rest. Better prenatal care and a keener regard for the clinical picture, together with the individualization of management and a realization by the medical profession that eclampsia and death are usually the result of neglect in the care of women who show changes in pregnancy which were thought unimportant, have been vital factors in the improvement in the mortality and morbidity statistics in toxemia.

Any classification of the toxemias of pregnancy must, because of the nature of the disease, be inadequate. The classification proposed by the American Committee on Maternal Welfare, although it does not cover completely all of the gradations of the toxemias, nevertheless does encompass the majority of them. The larger clinics and hos-

*Associate Professor of Obstetrics, Jefferson Medical College. Chief Gynecologist to St. Mary's and St. Agnes Hospitals, Philadelphia.

pitals are using it for study and correlation of findings The classification is as follows

- | | |
|--|-------------------------------------|
| 1 Hypertensive disease | 4 Eclampsia |
| 2 Renal disease | 5 Vomiting of pregnancy |
| 3 Preeclampsia, severe, preeclampsia, mild | 6 Acute yellow atrophy of the liver |
| | 7 Unclassified |

To anyone who is interested in obstetrics it is immediately recognizable that a clear-cut distinction between these different conditions is often difficult There is overlapping between the various groups Rather mild types of eclampsia can easily pass into the severe type of preeclampsia, and the severe type of preeclampsia can and does develop into eclampsia

Confusion also occurs frequently in the differentiation of hypertensive disease, preeclampsia and the acute exacerbation of chronic conditions This differentiation cannot always be made unless the patient is followed not only through the course of pregnancy but also through the postpartum period and for a number of months or even years thereafter Nevertheless, we have in this classification a satisfactory working basis and its universal adoption for the classification of toxemias is urgently to be sought, in order that some standard may be used throughout the country

THE ETIOLOGY OF TOXEMIA OF PREGNANCY

It has been contended by many that placental infarctions are either the cause of toxemia of pregnancy, or they may be used as a diagnostic criterion of maternal toxemia Hill and Tremble in 1944 studied the placentas from 640 deliveries which were fixed in 10 per cent formaldehyde solutions for from four to six weeks, then examined closely for certain infarcts involving the placental villi Forty-two placentas from patients with a definite clinical picture of toxemia were examined but only eight of these had infarcts which were extensive enough to be distinguishable from the placentas of nontoxemic patients Thirteen of the 598 placentas from patients with normal pregnancies showed infarcts like the eight from the patients with toxemia Hill and Tremble were unable to satisfy themselves that the acute type of infarct described by Bartholomew and his co-workers was associated with toxemia

The theory that the posterior pituitary factor plays an important role in the toxemias of pregnancy was presented by Mukherjee in 1941 This investigator relied upon the anatomical observations of Cushing and Ahlstrom that there was morphological evidence of hyperactivation of the neurohypophysis in toxemias of pregnancy, and the biological researches of Anselmino and others pointedly suggested the possibility of such functional hyperactivity

Mukherjee conducted a series of experiments in fifty unselected cases of pregnancy toxemia—two of eclampsia, forty of preeclampsia, one of nephritic toxemia, three of accidental hemorrhage and four of hyperemesis gravidarum. He found that the blood in these patients revealed ultrafiltrates which showed melanophoric, antidiuretic and vasopressor properties. The author believes that the toxemias of pregnancy are intrinsically one disease with varied manifestations. In his experiments he found the type of the diuretic and vasopressor responses corresponded roughly with the predominant clinical manifestations of the patients from whom the ultrafiltrates were obtained. For example in all of the hypertensive cases, marked and moderate vasopressor responses were obtained. The only substance present in the human circulation known to produce this triple response is the posterior pituitary hormone. Mukherjee studied fifteen normal pregnant women and they gave very little or no response whatsoever to the ultrafiltrates or pitressin, while fifteen toxemic pregnant women responded to pitressin and to the ultrafiltrates similarly—that is, by significant increase in blood pressure and by oliguria. It thus appears that there is an increased concentration of the posterior pituitary hormone in the circulation of toxemic patients. This was corroborated by the biochemical investigation in which it was found that the rise of blood uric acid and the lowering of carbon dioxide combining powers of blood to the extent met with in toxemia of pregnancy could be produced experimentally by large and repeated doses of the posterior pituitary extract in normal women. These facts suggest that an increased concentration of the posterior pituitary autotoxin, or functional hyperactivation of the pars nervosa of the hypophysis, in all probability plays a considerable role in the etiology of toxemia of pregnancy.

Mukherjee states that the most common residual lesion in toxemia of pregnancy is essential hypertension and not chronic nephritis as was formerly believed. The persistence of hyperactivation of the posterior pituitary lobe and chronic vasospasms may satisfactorily account for the sequelae. What stimulates this hyperactivation is difficult to explain. The toxic manifestations produced experimentally in normal pregnant women required extremely massive doses of vasopressin. It was found that with only a small dose of this substance, or the ultrafiltrate, worse toxemic symptoms could be produced in persons already suffering from pregnancy toxemia. These observations, the author feels, show that toxemic patients are in some degree susceptible to extracts from the posterior pituitary lobe.

These theories of the etiology of toxemia of pregnancy, together with the many other experimentations which have been reported, remain inconclusive. The only known definite cause for toxemia of pregnancy is the pregnancy, whether in a patient who has or has not had preexisting disease.

SYPHILIS AND TOXEMIA OF PREGNANCY

In our clinic at the Jefferson Medical College Hospital which has been conducted exclusively for the treatment of syphilitic pregnant women since 1925 we have found no greater incidence of toxemia of pregnancy than we have in the prenatal clinic as a whole. These findings agree with those of Peckham who in 1941 concluded that antisyphilitic treatment administered to the pregnant syphilitic woman during pregnancy does not increase the incidence of toxemia of pregnancy. This author found that, in a series of 13 742 consecutive deliveries at the Johns Hopkins Hospital, the incidence of toxemia of pregnancy was somewhat lower in syphilitic than in nonsyphilitic patients. He could find no correlation between the stage of syphilis at the time of its diagnosis and treatment during pregnancy and the frequency of toxemia. The incidence of toxemia was low-

est in a group of syphilitic women treated before pregnancy, but not during, slightly higher in patients not treated, since he found the diagnosis of syphilis was actually higher in the group receiving treatment for toxemia during pregnancy

Peckham thinks that these differences are all within the average of sampling error and the highest incidence in the treated group was well below that of the general clinic population. The amount of treatment employed was without significance. A number of patients had been treated in previous pregnancies without developing toxemia, and others were subsequently treated throughout one or more normal pregnancies. One-half of the treated patients evidenced toxemia before the first injection of an arsenical drug and no correlation was found between the development of physical signs and the specific number of injections previously given

LABORATORY TESTS IN THE TOXEMIAS OF PREGNANCY

It is the consensus that the clinical findings are of much greater importance in the management of toxemia of pregnancy than the laboratory tests. Kriger and Rome, after a study of 652 patients, concluded that an evaluation of renal efficiency with the use of tests for albumin in the urine and urea in the blood did not give sufficient information. High blood urea values occur only when the kidney damage has become pronounced. They also found that the urea concentration excretion and the Fowweather clearance test offered a valuable means for detecting the intermediate as well as gross degrees of kidney damage and give information regarding improvement or deterioration of the kidney function.

Cuizza in 1941 discussed the various tests for functional activity of the liver and kidney and gave in detail the technic for determining Maillard's coefficient.

Cuizza's report is based on eight cases of hyperemesis gravidarum, twenty-six cases of albuminuria and nephropathy in pregnancy, and eight cases of eclampsia. In hyperemesis gravidarum he finds that the organ most seriously injured is the liver as shown by acetonuria, urobilinuria and a high Maillard coefficient, which is a true coefficient of acidosis. On the other hand, kidney function is almost normal as shown by absence of albumin in tests of the urine, normal azotemia and low blood pressure. However, he found that in the nephropathies of pregnancy, kidney function is much more seriously impaired than the function of the liver as shown by albumin, casts in the urine, high azotemia and high blood pressure.

In eclampsia, the function of both the liver and kidneys is seriously impaired. All of the functional tests show more or less deviation from normal. The type of liver injury in eclampsia is different from that in hyperemesis gravidarum, particularly in the absence of acetonuria. The mechanism of the acidosis shown by the high Maillard coefficient differs in the two diseases. In hyperemesis it is due to the accumulation in the blood of ketone bodies which are intermediate products of the abnormal metabolism of fat, while in eclampsia it is due to the accumulation in the blood of intermediate acid products of protein metabolism, among which Zweifel demonstrated sacrolactic acid which was derived from muscle albumins. He believes, therefore, that his study confirms the theory that eclampsia is not merely an aggravated condition of pregnancy nephropathy, but is an essentially different disease marked by pathologic conditions in the liver also. None of the tests used in determining liver and kidney functions is decisive in itself, but

taken in conjunction with the others, and with the clinical findings, it gives a criterion of the function of these organs

As to Maillard's coefficient, it was found to be of decided value in hyperemesis, in which condition it shows the condition of the liver function and the degree of acidosis. It is of value not only in diagnosis but in prognosis. It helps one to determine when therapeutic interruption of pregnancy becomes necessary. It is of less value in nephropathy and eclampsia, in which conditions the decision must be based on the clinical more than the laboratory data. In eclampsia immediate action based on the clinical picture alone is often necessary

Krieger and Norris concluded, after a study of 3000 tests for renal efficiency during and after toxemic pregnancy, that the blood urea test is useful in indicating gross renal damage resulting from severe toxemia of pregnancy, or milder toxemias in association with chronic nephritis during the pregnancy. The urea concentration excretion test is a much more sensitive test than the blood urea test and enables less gross renal damage to be detected during toxemic pregnancy. It can also be used in recovery of renal efficiency, or to prove the presence or absence of permanent damage by observation of the results of tests at certain intervals for some months after delivery

They also found that the presence of albumin in the urine of a large number of patients whose kidneys had recovered normal function in relation to the excretion of urea in tests two months after pregnancy, and the persistence of traces of albumin in the urine of many of these patients even twelve months after delivery, showed that this is an even more delicate means of indicating that a kidney is not completely normal. Renal function tests, they feel, are of great value in the treatment of recurrent toxemia and, if investigations are carried on over a period of months after the initial toxemia, they will give information useful in the management of subsequent pregnancies.

A study of the urea concentration-excretion tests during and after pregnancy shows that the excretion of urea by the kidney is decreased slightly even by normal pregnancy. The recovery of normal function takes place often within eight days, and usually within two months of delivery. Maximum urea excretion is obtained. Recovery from eclampsia is slower, the maximum excretory power being regained within twelve months.

The contention that renal insufficiency can be detected in a greater number of patients before delivery rather than during the puerperium was disproved. Renal function did not deteriorate in the interval beginning eight days after delivery and ending twelve months after delivery in two-thirds of the patients investigated, and it improved during this period in practically all the remaining patients. Deterioration in renal function two months after delivery was rare. It is the consensus that an increase in the blood uric acid content is the most constant finding in toxemia of pregnancy. The reason for this is easily understood when one realizes that the kidney is an organ which has a great deal of reserve and that its impairment must be almost com-

plete before signs of it are found in the blood stream. Laboratory tests alone are therefore no criteria for the institution of treatment.

SYMPTOMS AND SIGNS

A number of symptoms and signs are more important in the diagnosis of toxemia than any of the laboratory studies, except perhaps the increase in blood uric acid.

Danger is imminent when a pregnant patient exhibits one or a combination of the following: (1) rising blood pressure, (2) increasing albuminuria, (3) rapid increase of weight, (4) diminished urine output, (5) increase in edema, (6) dimness of vision or amaurosis, (7) precordial pain, or girdle pain, (8) accelerated pulse, (9) increased depth of respiration, (10) torpor or excitability, (11) marked retinal edema.

TREATMENT OF THE TOXEMIAS OF PREGNANCY

Hypertensive Disease—In the management of hypertensive disease complicating pregnancy, it is the consensus that any pregnancy superimposed upon hypertensive disease is prone to make the hypertensive disease worse. So-called essential hypertension, of which we know very little, is nevertheless a clinical entity. Whether the pregnancy should be allowed to continue in a patient with hypertensive disease will depend entirely upon the clinical findings and the evaluation of the patient as a whole. It is the feeling of most that a patient with essential hypertension should not become impregnated. Nevertheless, in our clinic and in others, many patients with essential hypertension have been carried through a pregnancy under a regimen of individualization. We have in many instances been able, as have others, to bring the patient at least to the point where she may have a viable baby before termination of the pregnancy.

Renal Disease Complicating Pregnancy—A patient with definite existing renal damage who becomes impregnated not only jeopardizes her own life but also the life of the child she is carrying. She definitely should avoid pregnancy. True renal disease complicating pregnancy is considered by many experienced practitioners to be an indication for the termination of pregnancy, nevertheless, the patient's wishes and her religious beliefs should be taken into consideration. The added stress and strain of an already overtaxed cardiovascular renal tree is often most injurious to the patient. The management should be individualized.

Mild and Severe Preeclampsia—In the management of mild preeclampsia, one must always bear in mind that the mild type of eclampsia may become a toxemia of pregnancy with complete eclampsia. One should consider every preeclamptic a potential eclamptic. At the slightest sign of deviation from the normal the patient should be treated immediately and adequately.

The indications for the institution of treatment in preeclampsia are (1) increase in blood pressure, (2) increase in weight out of proportion to the usual gain, (3) edema of the hands, face and ankles, and (4) albuminuria.

What is an abnormal rise in blood pressure? To give any particular numerical figure as the top level at which the blood pressure is to be considered dangerous is to our mind a fallacy. It is normal for a person's blood pressure during pregnancy to be lower than usual. A blood pressure of 100/60 may be the normal pregnancy blood pressure in a certain patient, and if this rises to 130/80 it is abnormal for her. She may be in just as much danger as the person who began her pregnancy with a blood pressure of 120/80 and sustained a rise to 140/90. Another most important consideration is that the diastolic blood pressure is the more important of the two. A constantly raised diastolic pressure is to be considered dangerous.

It is the consensus that 20 to 25 pounds increase in weight for the entire pregnancy is a normal gain, which amounts to approximately 2 pounds a month. If the patient gains a pound a week or more, she should be seen more frequently.

Swelling of the face, ankles and hands is an indication of faulty elimination and water retention. This also calls for watchfulness.

The appearance of albumin in the urine should be considered abnormal. A catheterized specimen is necessary for the test, inasmuch as a voided specimen from a woman, especially a pregnant woman, is not reliable because the vaginal secretions collected with it obscure the picture.

Upon the appearance of any of the above signs and symptoms during the course of pregnancy the following routine should be immediately adopted:

1. The patient should be advised to rest every afternoon for at least one to two hours.

2. Salt intake should be drastically curtailed, a salt substitute may be ordered, such as "Curtasal." The patient gets the taste of salt but curtails her sodium chloride intake.

3. Enough of a saline cathartic should be used to give the patient a watery bowel movement. Either epsom salts, one teaspoonful in the morning, or enough to give her one watery bowel movement a day, should be taken. Many patients are much more cooperative if they are asked to take citrate of magnesia. Citrate of magnesia may be kept cool in the ice box. A wineglass full or two in the morning before breakfast is usually sufficient to produce a copious watery bowel movement.

4. A high protein, low carbohydrate diet is also prescribed.

5. The patient is seen at more frequent intervals.

In many cases this regimen will bring the blood pressure down, reduce the gain in weight, relieve the swelling of the ankles, face and

hands and reduce the amount of albuminuria. If there is no response to treatment, or if during treatment the patient complains of blurred vision or headache, or continues to gain weight, and experiences girdle pains or pains in the epigastrium, she should be hospitalized immediately. Home care in these circumstances is permissible only when a competent nurse can be in attendance to maintain complete control over her treatment.

Once the patient is hospitalized she should be placed on a high protein, low carbohydrate diet in order that the excess protein which is being excreted in the urine may be replaced. An eyeground examination is done to obtain a clear picture of the vascular tree. Daily catheterized specimens of urine, complete blood count, estimation of the uric acid content of the blood, and a chart of the daily intake and output are obtained. The patient is given a sedative, $\frac{1}{2}$ grain of phenobarbital three times a day is usually quite sufficient, or another sedative with similar action may be used. Complete bed rest is ordered, and the patient is placed between blankets so that she will sweat profusely. If the pathologic process is amenable to treatment, this regimen will ameliorate the symptoms present.

If after one or two days of this regimen the patient does not improve clinically, concentrated solutions of glucose are given intravenously. Two to five hundred cubic centimeters of 20 per cent glucose will usually stimulate the renal output. More highly concentrated solutions such as 50 per cent glucose used intravenously three or four times a day in conjunction with 2 to 5 cc of 25 per cent magnesium sulfate either intramuscularly, or given slowly intravenously, may be used to augment the above therapy in patients who do not respond. Plasma and whole blood are given intravenously only when indicated by the blood count reading and the blood protein globulin ratio. If the patient does not improve clinically under this regimen, then the toxemia is beyond medical care and the pregnancy should be terminated. The method of termination will depend entirely upon the parity of the patient and the type of cervix which is present. If the patient is a multipara and the cervix is soft, rupturing of the membranes under aseptic precautions after sensitizing the uterus by administering 2 ounces of castor oil the morning of the procedure will usually, after a short space of time, produce uterine contractions and institute labor.

During labor the patient should be given vitamin K for the protection of the premature child. Delivery is accomplished under some type of regional anesthesia, either local, spinal or caudal, and oxygen is administered to the mother during the time of delivery for the protection of the baby. When the cervix is completely dilated, outlet forceps, with episiotomy, are employed.

If the cervix is long and hard, especially if the patient is a primipara, induction of labor is not advised. The duration of labor may be long

and induction unsuccessful. In these instances a cesarean section is to be considered. A regional or a local type of anesthesia should be employed and no drug should be administered prior to the operative procedure which may narcotize the child. Oxygen is administered to the patient during the period of delivery as a protection to the child. Vitamin K is given to the child through its mother during the time that the patient is being prepared for the operative procedure and to the baby after its birth.

Eclampsia.—In the management of eclampsia the fundamental principles which were outlined above still obtain. Some patients will go into eclampsia no matter what therapy has been instituted to prevent it. Many are admitted to the hospital in eclampsia because of either inadequate treatment or lack of cooperation from the patient.

The most outstanding recent contribution in the therapeutic management of eclampsia is that of Rupert E. Arnell in January of 1945. Arnell reports a series of 142 consecutive cases of eclampsia without a maternal fatality. In the therapeutic regimen employed in this series nothing is either new or original, but details of treatment were carried out with meticulous care, to which is attributed the success which was achieved.

Arnell based his plan on ultraconservative concepts of management and the dangers of both overtreatment and indiscriminate treatment are evaluated. Constant observation of each eclamptic patient by an experienced staff throughout the entire course of treatment, which permitted careful integration of the various therapeutic components into an individualized regimen rather than application of a standardized routine of treatment, was the keynote of treatment.

Special factors of success also included frequent changes of posture, the use of oxygen therapy for respiratory stimulation during the acute stages of the disease, limitation of sedation to the dose necessary to control convulsions and hyperirritability, limitation of dextrose therapy to the smallest amount necessary to insure a satisfactory urinary output, with a return to oral fluids in a maximum amount, as soon as the swallowing reflex returned, delaying labor unless it occurred spontaneously, or until full recovery from the acute stages eventuated, induction of labor at the opportune time by the simplest possible method, medical induction being repeated if the first attempt was not successful, limitation of interference to an irreducible minimum, and the use of a local type anesthetic for all forms of operative work.

Arnell found that neither the future health nor subsequent pregnancies of patients were in any instance jeopardized by this plan of management. This statement is based upon observation of eighty-five patients at intervals of from five to fifteen weeks after delivery.

Adequate consideration of the baby yielded high dividends without increasing the maternal risk. The fetal mortality in this series was

24.2 per cent This showed marked improvement in the last two years, when the principles of consideration for the child were increasingly applied

Lack of adequate prophylaxis was the factor chiefly responsible for the resultant eclampsia in these 142 cases In this respect adequate care during gestation is not sufficient Intelligent care and judgment are needed during labor, at delivery, and throughout the puerperium

Vomiting of Pregnancy.—Vomiting of pregnancy may be either mild or severe Approximately 60 per cent of all patients have some gastrointestinal upset during the early months of their pregnancy Undoubtedly psychoneurologic tendencies are often a real factor in the aggravation of symptoms In any disease in which many therapeutic agents are proposed for the treatment, we may safely assume that none of them are completely successful

In the management of the early vomiting of pregnancy many agents have been used, among which may be mentioned injections of whole blood, vitamins, and the hormones The benefits from this therapy are debatable It probably is at least of some value psychologically. Personally I have discarded all types of injections except the injection of Vitamin B, for a period of five or six days The proper psychological approach during this early stage will in many instances prevent the development of pernicious nausea and vomiting The patient is made to realize that if she eats four times and vomits three times, one of the meals is retained, thus she is gaining and need not worry Too much concern by the family and especially the mother-in-law and the husband should be curtailed Small frequent meals, sedation and psychotherapy usually suffice

The slight nausea and vomiting of early pregnancy may develop into the pernicious type—an eventuality always to bear in mind If the patient's pulse rate starts to rise and her loss of weight is sufficient to cause alarm, she should be placed in a hospital immediately Here she should have complete rest, preferably in a private room or in a screened-off bed No visitors are allowed She is, in fact, completely segregated from the outside world

Our treatment consists, first, of a rectal suppository containing $1\frac{1}{2}$ grains of phenobarbital, given every four hours We give the patient nothing by mouth Fluids and amino acids are administered intravenously We use subcutaneous solutions for the discomfort they produce and impress upon the patient that just as soon as she is able to take fluids by mouth these therapeutic agents will be stopped Vitamin B complex, 100 mg, is given by injection intramuscularly daily

Irving has described a plan of treatment which has proved very successful at the Boston Lying-In Hospital and which incorporates the fundamental principles to be utilized in these cases Under this regimen the incidence of therapeutic abortion has been reduced from 17.3 to 2.6 per cent and the mortality rate from 5.5 per cent to 0

The patient is isolated and receives sedatives. Intravenous infusions of glucose solutions are administered as described above. In addition, a Levine tube is passed and treatment carried out according to the following routine:

- Hours 0 Levine tube passed and the stomach gently washed with a small amount of warm water
- Hours $\frac{1}{2}$ Murphy drip started 46 ounces of milk containing two heaping tea spoonfuls of Harris's yeast concentrate
- Hours $1\frac{1}{4}$ 4 to 6 ounces of orange juice sweetened with corn syrup
- Hours $2\frac{1}{4}$ 6 ounces of rich eggnog made with cream and egg
- Hours $3\frac{1}{2}$ Milk and Harris's yeast concentrate as above

This routine is repeated until fourteen out of the twenty-four hours are completed. Each feeding requires about forty minutes and is given at body temperature.

lutely negative, blood pressure will probably be normal or below normal and the characteristic eye changes of a cerebral tumor will likely be present X-ray study of the head will, in many instances, make the diagnosis clear

In *acute meningitis* the neurological signs are rather characteristic and these combined with a clinical history as well as a spinal puncture should promptly determine the true nature of this disease

Eclampsia is an extreme degree of preeclampsia in which the patient rapidly passes into deep drowsiness or coma The condition is often fatal and on postmortem examination the changes are characteristic of eclampsia

CONCLUSIONS

The etiology of the toxemias of pregnancy is not clear Their management has been greatly improved, the mortality rate having dropped from 20 to 5 per cent in the past several years

The meticulous care of the pregnant woman with the added early treatment of the clinical signs has greatly increased the number of live births in the toxemias of pregnancy

Syphilis complicating pregnancy is not a great factor in the causation of toxemia of pregnancy

Laboratory tests, although of some value, have not proved of sufficient importance to warrant reliance on their findings in the management of toxemia of pregnancy Determinations of the blood uric acid and albumin of the urine are the most reliable laboratory tests when coupled with clinical findings

The management of hyperemesis gravidarum along more fundamental lines has reduced the mortality rate to zero and the incidence of therapeutic abortion from 17.3 to 2.6 per cent.

Arnell has shown that mortality in eclampsia can be reduced to zero, if meticulous care and individualization of treatment for each patient is assiduously adhered to

The modern management of the toxemic pregnant woman is based on early treatment and the induction of labor when medical treatment does not produce amelioration of signs and symptoms

THE MANAGEMENT OF THE PREGNANT CARDIAC PATIENT

CHARLES W SEMISCH, III, M.D *

Few medical problems produce more diversification of general management than the patient with cardiac disease who becomes pregnant. The physician has not only clearly to evaluate the cardiac problem but must also consider the social, economic and religious factors. Any of the latter may alter sound medical judgment and lead to a doubtful procedure. The advice we must give to the patient who is childless may differ entirely from that which we give to a patient who already has one or more living children. One can readily see that each pregnant cardiac patient is a problem unto herself and decisions which hold for one will differ entirely for another.

In the past twenty years great stress has been laid upon the complications of pregnancy, particularly heart disease. Careful cooperation between the obstetrician and the cardiologist, together with the instigation of specified regular cardiac examinations, have negligibly lessened the maternal mortality.

The effects of pregnancy on the diseased heart must always be considered before pregnancy is advised. It is now well known that the work of the heart increases approximately 50 per cent during pregnancy and that this increase in work reaches its maximum at or about the eighth month. It is also known that the heart enlarges during pregnancy, that the blood volume increases, and that the minute output of blood increases as well as the velocity of the blood flow. The blood pressure generally falls during pregnancy, but may reach unexpected heights during labor. Since the basic principle of any cardiac problem is the reduction in the amount of heart work, it becomes necessary to appraise accurately each cardiac patient before or as soon after pregnancy occurs as is possible, and to separate those who can stand an increase in the cardiac load as contrasted to those who will probably have a break in compensation with the added burden of pregnancy. Of primary importance is the state of compensation of the circulation. If there has been previous decompensation or if the patient has evidence of heart failure when first seen, it is best to advise that pregnancy should not be contemplated or no further pregnancies undertaken.

PREGNANCY IN THE PRESENCE OF VARIOUS CARDIAC CONDITIONS

There are two general groups of cardiac patients who, we may assume, have a normal heart. I refer to those who have one of the types

Associate Cardiologist, Jefferson Medical College Hospital, Philadelphia.

of functional heart disease and those who have systolic mitral murmurs, either of doubtful or specific origin. Of the remaining cardiac patients subject to pregnancy, 90 per cent will have rheumatic valvular heart disease. The remaining ones will be divided among the hypertensive, congenital, syphilitic and coronary groups. Let us first consider the miscellaneous groups.

Hypertensive Disease.—In general, patients with an elevation of systolic and diastolic blood pressure do not tolerate pregnancy well. On occasions, the tremendous desire of the patient to have a child, or the religious aspects will alter our judgment and we may permit individuals who do not have a marked elevation of blood pressure (above 160–180/90–100) and, who do not have significant kidney and eye-ground changes, or a history of previous decompensation to go through one pregnancy. However, it is a known fact that following the pregnancy hypertension usually increases and the life expectancy of the individual is shortened.

Congenital Heart Disease.—This group is divided into two principal classes, namely the cyanotic and acyanotic groups. The cyanotic group should never become pregnant and if they do, therapeutic interruption is mandatory. The acyanotic group (provided there has been no history of previous decompensation) can generally tolerate pregnancy fairly well and subsequent pregnancies will depend on whether the patient developed heart failure and whether there was an increase in the degree of cardiac damage. I have personally observed a woman who has had a patent ductus arteriosus go through four pregnancies without a mishap.

Syphilitic Heart Disease.—Since vascular syphilis has a predilection for the aortic valve, luetic heart disease if complicated by pregnancy has potential aortic valvular disease as the main factor. These patients usually tolerate pregnancy well, provided that the aortic insufficiency is an early lesion. If aortic insufficiency can be clearly demonstrated and there is no history of a previous break in compensation, one pregnancy may be permitted—other factors excluded. A history of previous decompensation is an indication for the interruption of the pregnancy. Aneurysm is a definite contraindication to pregnancy and therapeutic interference should be done at once.

Coronary Disease.—Coronary disease in my opinion is a definite contraindication to pregnancy, and early therapeutic abortion must be strongly urged.

Cor Pulmonale.—It has been shown that pregnancy does not interfere with the vital capacity in the later months of pregnancy, and since the burden of the work would have to be done by the left ventricle, it will not harm a patient with longstanding pulmonary disease and right-sided enlargement to go through pregnancy. In fact, our experiences have shown that pregnant patients are quite comfortable during the latter months of their pregnancy.

Rheumatic Heart Disease—Most of the patients with rheumatic heart disease who become pregnant will have mitral insufficiency, characterized by a rough-blowing systolic apical murmur, usually of a grade 2 or 2 plus or more. If there is no history of previous decompensation, these patients tolerate pregnancy well and can be considered as normal subjects. A small percentage will subsequently develop heart failure. Our main problem is with women who have mitral stenosis or aortic disease or both. Here again, the history of previous decompensation, the size of the heart, the electrocardiographic evidence of no to marked myocardial impairment must influence one's decisions, for a previous history of failure or marked cardiac enlargement is a definite contraindication to pregnancy. The patient with acute rheumatic fever or auricular fibrillation should not contemplate pregnancy. Auricular fibrillation that develops during early pregnancy is likewise an indication for therapeutic interruption. It is generally agreed that abortion in the early months of pregnancy does not preclude the same dangers that it does in the later months. It is therefore important that our decisions be made early, for the procedure is comparatively harmless during the first three months. It has been our policy to permit patients with mitral stenosis with no decompensation or history of failure to go through one pregnancy. Subacute bacterial endocarditis definitely is a contraindication to pregnancy.

The concepts noted above are, of course, generalities and there are many other personal, social, economic and religious factors which will alter one's sound judgment. When possible, even when the exact state of the heart is in doubt, the wish of the patient may warrant a slight added risk, for the joy of having a child is a great contrast to a childless life.

THE GENERAL MANAGEMENT OF THE PREGNANT CARDIAC PATIENT

There are three periods in the course of pregnancy during which decompensation is most apt to occur. It may first be detected about the fourth to the fifth month, or at the time that corresponds to the formation of the placenta, which functions as an arteriovenous anastomosis. It is at this time that the first appreciable increase in cardiac work occurs. Between the seventh and eighth month is the second period during which heart failure is most apt to occur, or at the time at which the cardiac load has reached its peak. The third period in which a break in compensation may occur is during labor itself. This produces a sudden tremendous load upon the myocardium and breaks in compensation that occur are apt to be sudden and of the left ventricular type.

The cardiologist's part *in pregnancy* is two-fold (1) he must appraise any existing cardiac lesion and the state of the myocardium (2) if it is damaged, he must attempt to lessen the amount of cardiac

work by careful instruction and guidance. It has been my policy to place all pregnant cardiac patients routinely on the following regimen:

- 1 A low caloric diet, poor in salt and high in vitamins, is advised. The patient is cautioned not to exceed the usual gain of 20 pounds during pregnancy. Salt and water retention and an increase in weight are definite burdens on the myocardium.
- 2 Proteins are given freely, since hypoproteinemia and resulting edema can also produce an increase in the myocardial load.
- 3 Ferrous sulfate is given in a dosage of 6 grains three times a day to combat or prevent the anemia of pregnancy, for it is well known that a diminution in the number of red cells produces an increase in cardiac effort.
- 4 Tight supports are prohibited.
- 5 Activities are restricted and specified rest periods are strongly advised.

When heart failure occurs in patients with heart disease, it is usually manifested by increasing dyspnea, cough, swollen ankles, and basal rales. If failure occurs early in pregnancy and is severe, interruption of the pregnancy is strongly advised. If it occurs during the second trimester our decision is more difficult. One must consider the degree of failure and the viability of the child. It may be necessary to perform an abortion at the fourth, fifth or sixth month. Sometimes the outlook will not be favorable regardless of the course pursued. When failure is detected, these patients are placed upon the following regimen:

- 1 Bed rest (absolute and complete) is ordered.
- 2 The general measures mentioned previously must be adhered to rigidly. If the symptoms of failure do not subside in four or five days, digitalis must be given. If the failure is severe, the more rapid methods of digitalization are indicated. It is my practice to give 0.5 to 1 *cat* unit of digitalis per day throughout the remainder of her pregnancy.

It should be borne in mind that maintenance doses of digitalis must be adequate and that this is truly an individual issue. There are some who believe that digitalis need not be given, but I personally feel that it is more beneficial than harmful.

Women who have had decompensation during the first and second trimester are placed on almost absolute bed rest during the last few months. Arrhythmias that may develop after the fourth or fifth month, namely, paroxysmal tachycardia, auricular fibrillation, or frequent extrasystoles can usually be successfully managed by the use of small doses of quinidine. Calcium gluconate intravenously may control severe paroxysms. Persistent arrhythmias, I believe, are definite indications for therapeutic interruptions regardless of the period of gesta-

tion. Patients who present failure in the last trimester are best delivered by elective caesarean section

Heart failure *during labor* is usually of a sudden precipitous nature and is manifested by sudden pulmonary edema, cyanosis and hemoptysis (acute left ventricular failure). This is best managed by morphine, oxygen, phlebotomy and, if no digitalis has been taken during the previous three weeks, ouabain, 0.5 mg intravenously, is given. This is followed in two or three hours by one large dose of digitalis parenterally, usually 3 to 5 cat units. Two or 3 cat units by mouth every six hours for two to three days may then be given. Sudden breaks in compensation during the puerperium are usually of the same variety as just mentioned and are treated in the same manner.

The *choice of an anesthetic*, if needed, is largely an obstetrical problem. In general, cardiac patients do well with ether. Recently, caudal anesthesia has proved very satisfactory. It has been our custom in patients who present decompensation at or near term to do a caesarean section under local anesthesia, particularly in the primiparous patient. Caudal anesthesia has also been beneficial in delivery by the vaginal route since it reduces the added stress of labor to an almost negligible factor.

In severe cardiac patients, the problem of *sterilization* almost always arises and I should like to state definitely that caesarean section should never be done with the purpose of ligating the tubes at the time of operation. One has no assurance that the child will survive delivery or even the first year of life. One may find later that the first pregnancy was tolerated quite well and a second child may be desired. If the first attempt to have a child is uncomplicated, it is strongly advised that the patient become pregnant as soon as possible since the added load is borne far better in the early years than later. Furthermore, the mother will have a longer period in which to enjoy her children. Sterilization should be advised only when it is certain that under no circumstance will the mother be allowed to go through further pregnancies.

It is always well to keep in mind that every cardiac patient is an individual problem and that when pregnancy occurs the problem is even more personal. Therapy and procedure for one individual with a given lesion will differ entirely from that of another similar individual. In general, if one must err, it is far better to err on the safe side. However, in conclusion, it must be always remembered that there is no other problem in medicine in which the patient's wish and desire must be so strongly heeded, in which sound clinical judgment is so often willfully ignored.

PREGNANCY AND TUBERCULOSIS

DAVID A. COOPER, M.D., F.A.C.P.*

INFLUENCE OF PREGNANCY ON TUBERCULOSIS

THE influence of pregnancy on tuberculosis is a complex problem and one that has been discussed pro and con for many years. It is still far from being entirely settled. That this state of affairs persists is understandable, if we appreciate the varied manifestations and reactions of the individual to tuberculosis, and add to this the variable reaction of the individual woman to pregnancy. Krause,¹ in an editorial on the subject a few years ago, summed up the problem with this question, "May it not be that pregnancy exerts a harmful effect on tuberculosis in those women who, without tuberculosis, would naturally tolerate pregnancy poorly, and a harmless, or even beneficial effect on those women, who, without tuberculosis, would stand pregnancy well, or even have their bodily economy improved by pregnancy?"

The literature on the subject is extensive and, in the earlier writings, pregnancy was recommended as a therapeutic measure for tuberculous girls. Later, we find that the pendulum had swung to the opposite extreme, as is so often the case in medical thinking, to such an extent that abortion was advised in every pregnancy occurring in a tuberculous patient. In recent years, this point of view has been modified and there is considerable evidence to justify it. However, as late as 1936, DeLee² stated that until it can be incontestably proved that pregnancy actually improves the tuberculosis, the course of early interruption in every case of active tuberculosis is most charitable.

What, then, are the basic facts in this problem? The first is the difference in the tuberculosis mortality curve in females during the childbearing period, when compared to the male mortality curve of the same age group. In the two sexes the death rate runs parallel until the age 15, when there is a sharp rise in the female mortality curve, with a high plateau, until age 35, when there is a rather abrupt drop, whereas, in the male, there is a gradual rise, which continues well past this age. This fact in itself suggests a definite relationship between childbearing and tuberculosis incidence and mortality. In the city of Philadelphia, 20 per cent of deaths among women in the childbearing

* Associate Professor of Medicine, Graduate School of Medicine, and Assistant Professor of Medicine, School of Medicine, University of Pennsylvania, Physician, Pennsylvania and Philadelphia General Hospitals, Assistant Physician, University of Pennsylvania Hospital

Within the past few decades, a number of *experimental studies* have been carried out in an attempt to solve the problem of the influence of pregnancy on tuberculosis. In 1916, Norris⁸ stated that pregnancy definitely shortens the life span of tuberculous guinea pigs, and in 1917 Theobald Smith⁹ stated that, in cattle, parturition is frequently followed by generalization of a local tuberculosis, with speedy decline and death. Mueller,¹⁰ in 1923, concluded that pregnancy has a favorable influence on the course of tuberculosis in guinea pigs. Burke¹¹ in 1940 and Wade¹² in 1942, studying the influence of pregnancy on experimental tuberculosis in rabbits, concluded that the course of tuberculosis was not appreciably influenced by pregnancy. Within the past few years a number of studies have been carried out on the influence of various hormones on experimental tuberculosis in animals. In 1937, Steinbach and Klein¹³ reported that antuitrin-S exerts a beneficial influence on experimental tuberculosis. Brack and Gray¹⁴ were unable to detect any effect on resistance to tuberculosis in animals, kept in a high state of hyperestrinism. Long and Vogt¹⁵ found no significant effect of gonadotropic hormones upon tuberculosis in mice. Carnes and Biskand¹⁶ obtained no appreciable effect from treating tuberculous animals with testosterone propionate. Green and Morgan¹⁷ obtained no effect from injections of progesterone in tuberculous male guinea pigs. Lurie,¹⁸ in a recent unpublished study, using inbred rabbits of low, genetic resistance to tuberculosis found that estrogen uniformly retards the progress of the disease at the site of inoculation, in the draining lymph nodes and in the internal organs. That the rabbits injected with estradiol were actually under the physiologic influence of estrogen was demonstrated by the fact that the uterus of the estrogen-treated rabbits weighed much more than the uterus of the corresponding litter mates, which had not received the hormones. He concludes, therefore, that estrogen increases resistance to tuberculosis.

In similar experiments performed on highly inbred rabbits of high genetic resistance to tuberculosis, with the purpose of determining the effect of corpus luteum hormone on the progress of the disease, the following observations were made. To obtain a continuous, natural corpus luteum effect, experimental animals received from 0.02 to 0.1 mg of chorionic gonadotropin intravenously every tenth day, and a control group received none. It was found that, in the majority of instances, the presence of corpus luteum or corpus lutea cells in the ovaries was associated with an enhancement of the tuberculosis at the site of the inoculation and in the internal organs, as compared with the untreated controls. Furthermore, the number of organs to which the disease has spread was markedly increased in the rabbits treated with the hormones as compared with the controls. It is noteworthy that the intensity of development of tuberculin sensitivity was conspicuously retarded in the animals under the influence of corpus luteum hormone, since it has been shown previously that, in rabbits of low genetic resistance to the disease, the development of tuberculin sensitivity in response to heat-killed tubercle bacilli is markedly slower than in animals of high genetic resistance. It is clear that the presence of corpora lutea in the ovary is associated, not only with an enhancement of the tuberculous process and acceleration of dissemination of the disease, but also with a fundamental alteration in the response of the animals to the infection in the direction of increasing susceptibility. If these hormones exercise similar effects in the human being, one may expect that, during the estrogen phase of the menstrual cycle, the progress of tuberculosis should be retarded, whereas, during the corpus luteum phase of the cycle, dissemination of the disease would tend to be accelerated. Likewise, in the first month of pregnancy, when the corpora lutea are most active, the disease would tend to spread.

These experimental studies tend to confirm the clinical impression that has developed from observing the influence of pregnancy on

tuberculosis They also give a clue to some of the confusing factors that play a part in tuberculosis complicated by pregnancy That other factors are present there seems little doubt Pregnancy, in itself, induces physical and mental stress and strain and, if our present concept of the treatment of tuberculosis is correct, these additional factors of stress and strain predispose to the activation or reactivation of a latent or healed tuberculosis

It is generally accepted that a nutritional factor is associated with resistance to tuberculosis Nausea and vomiting in the early months of pregnancy may be severe enough to interfere with normal nutrition and thus could be a factor in the reactivation of a latent tuberculosis In my own experience clinical evidence tends to support this theory Nausea and vomiting not only affect nutrition but cause loss of sleep and rest, thus contributing additionally to the reactivation of a latent tuberculosis

That the rising diaphragm, during the latter months of pregnancy, has a beneficial influence on the course of the tuberculosis is borne out by clinical experience, as is the claim that its sudden descent, following delivery, has a deleterious effect.

Various *chemical changes in the blood* during pregnancy have been mentioned as having an untoward influence on the course of the tuberculosis. The most notable among these is blood calcium but at the present time there is no valid proof that a calcium deficiency contributes to the lowering of resistance to the tubercle bacillus. The high blood cholesterol associated with pregnancy has been suggested as a factor but in other conditions in which hypercholesterinemia is present, there is no demonstrable increase in susceptibility. The view has been expressed that the loss of fluid such as blood and milk, during and after delivery, explains the increase in tuberculous activity which may occur at that time. Tuberculin energy which is said to occur in pregnancy has been suggested as a factor in the reactivation or progression of tuberculosis this evidence, however is rather inconclusive. The long muscular strain, loss of blood and exhaustion associated with a long labor may well be a factor in the reactivation of a latent tuberculosis. Jamison¹⁹ has suggested that increase in the capillary permeability associated with pregnancy might have a possible deleterious effect upon the tuberculous woman. The capillary permeability increases up to about the seventh month of pregnancy and then decreases toward the end of gestation, only to undergo a sudden rise that attains its highest point on the third and fourth day postpartum. It has been suggested that the proteolytic ferment concerned with the involution of the uterus may act in the same way and cause a reactivation of a tuberculosis, with softening of the focus.

In view of all of these factors that might influence tuberculosis in the pregnant woman, it is surprising to find that adequately treated tuberculosis withstands pregnancy well. Ornsteen and Covnat,²⁰ reporting on the influence of pregnancy on pulmonary tuberculosis, report a group in which eighty-five tuberculous pregnant patients were studied. Of these, thirty-one (36 per cent) died, in fifteen (18 per cent) the tuberculous process was unimproved or progressed, and in thirty-nine (46 per cent) it improved. In other words,

54 per cent of their patients died or did poorly. These findings alone seemed to indicate that pregnancy has a deleterious effect on tuberculosis, but in comparing these statistics with those of a group of female patients with tuberculosis uncomplicated by pregnancy they found that in the latter group 33 per cent died, 31 per cent were unimproved and 36 per cent were improved. They concluded therefore that the pregnant woman with tuberculosis stands as good a chance as her nonpregnant sister. They went further and classified the group of cases, not only as to the extent of disease, but also as to type of disease and concluded as follows, "All our deaths in the pregnant series at the Seaview Hospital were in the caseous-pneumonic group. On the other hand, in the resolving, exudative and chronic productive group, in which the prognosis is better and usually good, there were no deaths in the hospital in thirty-four such cases, and all of these patients were discharged improved. Pregnancy had only a minor effect on the prognosis of the disease in the caseous-pneumonic group, for which it shortened the usual span of life, compared with the nonpregnant group." In a subsequent study of eighty-two pregnant, tuberculous women by Ornsteen and Epstein,²¹ there were fifty-nine cases of caseous-pneumonic tuberculosis, eight cases of resolving, exudative tuberculosis, and fifteen cases of chronic, productive tuberculosis. There were ten deaths, all of which were in the cavity type of disease. Collapse therapy was done in forty-seven out of forty-nine cavity cases. In twenty cases in which the cavity was closed with pneumothorax therapy the women were discharged from the hospital with negative sputum. Among thirteen women in whom the cavity was not collapsed by pneumothorax, nine died, in one the tuberculous process progressed and in three it was unchanged. In fourteen cases in which thoracoplasty was done, thirteen patients were discharged with arrested cases of pulmonary tuberculosis and one case was unchanged. In the remaining twelve cases, no surgical treatment was used and one patient died, in five the condition was unchanged and in six it was improved. In the eight cases of resolving, exudative tuberculosis, all of the women were discharged with negative sputum. In the fifteen cases of chronic, productive tuberculosis, all patients were discharged with negative sputum. On the basis of the above, Ornsteen and Covnat conclude that pregnancy has no influence on the course of pulmonary tuberculosis, and that the prognosis depends upon the character and control of the pulmonary tuberculosis, not upon the complicating pregnancy. The death rate among eighty-two tuberculous, pregnant women was reduced, with the aid of collapse therapy, to 12.2 per cent.

Mariette, Lawson and Litzenberg,²² reviewing twenty years' experience in the management of pregnant tuberculous women at the Glen Lakes Sanatorium, in which they have had ninety-six full term pregnancies in eighty-six tuberculous women, with a mortality rate of 18.3 per cent, which compares favorably with a mortality rate of

39 per cent in nonpregnant tuberculous women in the age group 18 to 39 years, concluded that treatment of the pregnant woman with tuberculosis by modern methods of combating the disease, together with good prenatal care, apparently offers her as good a chance of recovery from her tuberculosis as though pregnancy did not exist.

MANAGEMENT OF THE PREGNANT TUBERCULOUS WOMAN

Before going into the details of management of recognized tuberculosis complicated by pregnancy, the importance of unrecognized tuberculosis should be stressed. It is in this group that so many of the pathetic cases fall, in which a pregnancy is followed by a rapidly progressive and fatal tuberculosis. An appreciation of the high incidence and mortality of tuberculosis during the childbearing age should make the obstetrician tuberculosis conscious. The following case is a good example of the dire results of unrecognized and untreated tuberculosis, associated with pregnancy.

The patient was white and gave a history of having had a "spot on her lung" at 19 years of age, which was said to have healed. She was married six years later and two years thereafter became pregnant. She went through her pregnancy normally except that she felt that it took a great deal out of her. Following delivery she failed to regain her strength and continued to lose weight and had an afternoon fever with cough and sputum. A chest x ray at that time showed extensive tuberculosis of an acute, exudative type and shortly thereafter she developed a hematogenous dissemination and died.

Had this situation been appreciated early during the pregnancy, the end results might have been prevented. Most experienced obstetricians have observed this same sequence of events, and that is why so many obstetricians favor interruption of pregnancy when associated with tuberculosis.

At this time, when so much is written about the prenatal care of patients, the importance of some form of roentgen examination of the chest as a method of finding tuberculosis cannot be too strongly stressed. A roentgen examination of the chest of the pregnant woman is just as important as the routine Wassermann test and, with the modern methods of examination, just as simple and economical. The physical examination alone is no longer considered adequate to rule out the presence of significant pulmonary tuberculosis. The 14 by 17 inch celluloid film is undoubtedly the best, but also the most expensive, method of chest roentgenography. Any of the accepted miniature film photofluorographic methods are quite satisfactory and quite economical. The fluoroscope also is of value, but it has a number of disadvantages, namely, visual limitation, the personal equation and the lack of a permanent record. When a routine roentgen examination of the chest becomes a part of a prenatal examination, we will have gone a long way toward controlling the problem of tuberculosis and pregnancy, because it has been well shown and is generally accepted that

a patient with recognized tuberculosis, if the disease is rigidly treated tolerates pregnancy well

The management of tuberculosis complicated by pregnancy dependent upon a number of factors. The first is the extent and type of disease. A woman with known tuberculosis, whose disease has been arrested for a period of from three to five years and is not too extensive, can usually stand pregnancy without difficulty. She should, however, be under medical supervision during the entire course of pregnancy and for at least a year thereafter, and her disease should be followed by serial chest roentgenograms. For those who develop tuberculosis early in their pregnancy, the question always comes up to whether or not pregnancy should be interrupted. At the present time a hard and fast rule should not be made. The general trend is certainly away from abortion, and it should be brought out that therapeutic termination of a pregnancy in a tuberculous woman is without danger. All of the many factors should be carefully weighed before any conclusion is reached. If the disease is recognized early in the pregnancy, it is perfectly reasonable to put the patient on treatment and observe her for a period of from four to six weeks before a decision is reached.

A general rule for the management of tuberculosis complicated by pregnancy is that the disease should be treated much more rigidly than the uncomplicated case. For instance, if there is a question of induction of pneumothorax or some other collapse procedure, pregnancy should force the indication, rather than delay it.

In the acute, caseous, pneumonic type of tuberculosis, in which pregnancy is discovered early, I have in the past made a practice of advising interruption of the pregnancy. However, I have frequently seen that, in spite of interruption of the pregnancy and the induction of some form of collapse, the disease has progressed, perhaps more rapidly than it would have otherwise. If patients are past the third month in their pregnancy when tuberculosis is discovered, interruption is rarely, if ever, justified. The disease should be treated rigidly and some form of collapse therapy instituted if it is possible or feasible and the patient allowed to go to term. It is amazing how well patients with far advanced pulmonary tuberculosis tolerate pregnancy. Their condition will frequently improve, or, at least, remain stationary, during the latter months and the patients will go through labor normally. A percentage of them will take a downhill course several months later, but it should be emphasized that this is the natural course of the disease and not necessarily a result of the pregnancy.

Bed rest with adequate nutrition, supplemented by the various collapse procedures, such as pneumothorax, phrenic nerve interruption and thoracoplasty when indicated, forms the basis for the present management of tuberculosis. It has been adequately demonstrated that

tuberculosis when complicated by pregnancy, if properly treated, behaves about as well as though pregnancy had not occurred

At the present writing, there is no chemotherapeutic substance that has been accepted as being of value in the treatment of tuberculosis, whether it is complicated by pregnancy or not. The drugs of the sulfone group are, at the present time, too toxic for clinical use. In the field of antibiotics the future is pregnant with possibilities, but there is as yet no substance of proved, clinical value

In dealing with pregnancy that is complicated by tuberculosis, the question usually arises as to whether or not early induction of labor or cesarean section is advisable. From the standpoint of the phthysiologist, labor and delivery should be made as easy and short as possible by whichever method, in the opinion of the obstetrician, is the least shocking and in which there is the least amount of trauma to the patient. In our experience patients generally have been allowed to go to term and deliver normally, with the exception of the use of mid or outlet forceps. A general anesthetic, particularly in open cases of tuberculosis, is inadvisable. Caudal anesthesia fulfills the indications and has been quite satisfactory when employed

CONCLUSIONS

1 Statistical evidence indicates that more than an accidental relationship exists between childbearing and the high tuberculosis incidence and mortality rate during the childbearing period of women.

2 A high percentage of tuberculous women associate the onset of their tuberculosis with a pregnancy. The prenatal clinic is a better than average agent for tuberculosis case finding.

3 Two groups of factors associated with childbearing may influence the course of tuberculosis: (a) Specific. Estrogen has a favorable influence and progesterone an unfavorable influence on resistance to tuberculosis in experimental animals. (b) Nonspecific. Lack of rest, food and sleep may result from pregnancy and its complications and exert an unfavorable influence on tuberculosis.

4 The prognosis of tuberculosis complicated by pregnancy is more dependent on the control of the tuberculosis than on the associated pregnancy.

5 Even though the consensus is that pregnancy is an added hazard to the tuberculous woman, the indiscriminate interruption of pregnancy, because of tuberculosis, does not seem to be justified.

6 With adequate treatment most patients with tuberculosis tolerate pregnancy well.

RECENT ADVANCES IN THE MANAGEMENT OF THE SYPHILITIC PREGNANT WOMAN

HERMAN BEERMAN, M.D., Sc.D (MED)*

AND

NORMAN R. INGRAHAM JR., M.D.†

PREVENTION and treatment of syphilis in the pregnant woman, one of the most efficient approaches of the public health movement to control this disease, has made many advances in the past decade. Within a relatively short time case finding has been stimulated by the enactment in various states of premarital and prenatal examination laws, a better understanding of the fundamental principles of treatment of the syphilitic pregnant woman have been attained, new drugs and methods of treatment have been introduced, and the diagnosis of syphilis in the infant has been placed on a more or less sound foundation. As a result of these advances, practitioners now have at their command practical means for elimination of congenital syphilis.

PATHOGENESIS OF SYPHILIS IN THE PREGNANT WOMAN

In order to properly treat syphilis in pregnancy it is necessary to know the pathogenesis of the disease in the pregnant woman. There is now general agreement that syphilis is practically exclusively transmitted to the fetus by the mother. This view is based on the following advances in our knowledge of this subject:

1 The mother, if not infected at the time of conception, may readily be inoculated via the uterine cavity. She is invariably infected, therefore, when her child is diseased.

2 The mother has positive blood serologic reactions for syphilis or some other evidence of the disease in *almost* every case in which the child is infected.¹

3 Most evidence seems to show that the fetus is infected in the later months of pregnancy and not close to the time of conception.

From the Department of Dermatology and Syphilology, School of Medicine and the Institute for the Control of Syphilis, University of Pennsylvania (John H. Stokes, M.D., Director).

Assistant Professor of Dermatology and Syphilology, School of Medicine and Graduate School of Medicine, and Assistant Director Institute for the Control of Syphilis, University of Pennsylvania. Assistant Chief of Clinic of Cutaneous Medicine and Syphilology, University of Pennsylvania Hospital.

† Assistant Professor of Dermatology and Syphilology, School of Medicine and Associate Director Institute for the Control of Syphilis, University of Pennsylvania. Chief of Syphilis Clinic, Philadelphia General Hospital. Chief Division of Venereal Disease Control, Department of Public Health, Philadelphia.

These facts may be summarized as follows (a) Spontaneous abortion (prior to the fourth month of gestation) occurs with about the same frequency among syphilitic and nonsyphilitic mothers. Similarly, late miscarriage has a noticeably greater incidence among known syphilitic parents. (b) Antepartum therapy for syphilis can assure the birth of a healthy infant in almost 100 per cent of cases, if it is continued throughout the later half of pregnancy only. (c) No embryo which contained spirochetes has been shown prior to the sixteenth week of fetal life (cf Hoffmann, Dippel²). Histologic changes in the embryo suggestive of syphilis have been described prior to the fourth month but *Spirochaeta pallida* has not been found, which must cast some doubt on the syphilitic nature of these lesions. (d) Syphilitic skeletal changes have not been shown to occur prior to the sixth lunar month, which would indicate that infection of the fetus had occurred not earlier than the fourth lunar month³.

The maternal portion of the placenta may be infected as a result of the occasional showers of *Spirochaeta pallida* which gains access to the blood stream of the mother, as in any active syphilitic infection. In general, the more recent the mother's infection with syphilis, the longer, more intense the bouts of spirochetemia and therefore, the greater the chance of infection of the fetus⁴.

DIAGNOSIS OF SYPHILIS IN THE PREGNANT WOMAN

The pregnant woman with syphilis is usually unaware of her infection. If history alone is depended on, about 90 per cent of the cases would be lost. It is not only because of poor observation on the part of the mother that she may not know she is diseased, but because the early manifestations themselves may be rather insignificant. The initial lesion may be on the cervix, labial lesions may be small and painless, or no lesions may appear at any time, and pregnancy may have a definitely modifying effect on the development of the florid lesions. Accordingly, routine blood testing of all pregnant women, as recognized in the prenatal blood test laws, becomes a matter of great moment. Various authors have found signs, symptoms or history of syphilis in 25 to 64 per cent of mothers. The points in the history which Ingraham (1935) found to be of greatest value were (1) treatment prior to pregnancy (46 per cent), (2) occurrence of late miscarriage or neonatal death in earlier pregnancies (35 per cent), (3) story of symptoms suggestive of syphilis (25 per cent), and (4) syphilis in other members of the family (21 per cent). Diagnostic physical signs of syphilis were present in the mother in only 10 per cent, but there was suggestive evidence in an additional 13 per cent.

The serologic tests on syphilitic pregnant women will give results depending on the age of the syphilis in the patient. The earlier the infection, the higher the proportion of positive results. Young women are more likely to have an untreated recently acquired infection in

which positive laboratory findings are readily obtained. The serologic tests in syphilis are generally reliable. The strongly positive serologic reaction in the pregnant woman, verified on repetition, is diagnostic of the disease. Women with doubtful or weakly positive serologic reactions during pregnancy with no other evidence of the disease and negative history will in the majority of cases show no evidence of syphilis, even on prolonged study. This is not different from the same situation when doubtful reactions are encountered in nonpregnant healthy individuals in whom the disease is never proven. Stokes and Ingraham⁵ found, from the Philadelphia General Hospital material, that the diagnostic error in terms of positive reactions from causes other than active syphilis based on follow-up of the infants of these untreated mothers was less than one per cent.

The question of biologic false positive reactions in syphilis has had some recent discussion in the literature (Beerman⁶). Spiegler found only 0.45 per cent positive reactions among 6580 patients. In the 1934 serology conference, the standard tests with the exception of the Hinton, gave no such reactions in fifty-four patients. The Hinton test yielded a very small number of such reactions. Kandler in 1940 concluded from an experience of 10,354 pregnant women, that there is no evidence that pregnancy impairs the sensitivity or specificity of the tests. Our experience concurs with this conclusion.

In view of the relative reliability of the serologic tests for syphilis in pregnancy, the practice of performing routine blood serologic tests for syphilis on every pregnant woman at the time of her first prenatal visit, as is required by many states, has uncovered a number of patients with latent syphilis and has given us the first reliable data on the incidence of syphilis in the pregnant woman. One such survey, based on 48,800 routine antepartum blood tests on the general population in New Jersey, showed 1.19 positive results. The taking of a single blood test at the time of the first prenatal visit, as desirable and valuable as it is, will not uncover all syphilis in pregnancy. Syphilis may be acquired at the time of conception, or even in the later months of pregnancy. Such women may or may not present symptoms, depending upon the duration of their infections and the development of the normal clinical course of their disease, prior to delivery. Therefore, a negative serologic reaction early in pregnancy should not exclude syphilis, especially if suspicious signs develop at a later date. To uncover all these cases, it is recommended that every pregnant woman have, in addition to the blood test at the time of the first prenatal visit, a repetition of this test at or near term.

TREATMENT OF SYPHILIS IN PREGNANCY

For the past two decades, numerous authorities (Williams 1920, McCord 1930, 1935, Jeans and Cooke 1930, McKelvey and Turner 1934, Cole, et al 1934, 1936, Ingraham 1938, Halloran 1939, Dill, Stander

and Isenhour 1940, Benensohn 1942, Boas and Gammeltoft in Denmark, Nabarro and Findlay in England, Hoffman in Germany) have shown that syphilis transmitted from parent to offspring is practically a preventable disease and that its prevention depends upon diagnosis and treatment of syphilis in the pregnant woman. In order to have effective treatment, a drug which has strong spirillicidal action must be used. Such preparations are neoarsphenamine, arsenoxide (mapharsen, dichlorophenarsine hydrochloride) or the newly introduced penicillin. Heavy metals alone, bismuth or mercury, are ineffectual. Recent observations have indicated that certain principles must be followed in the treatment of the syphilitic pregnant woman if the greatest advantage is to be obtained from the antisyphilis remedies. These principles are given as follows:

PRINCIPLES OF TREATMENT OF THE SYPHILITIC PREGNANT WOMAN*

- 1 Begin treatment of the syphilitic pregnant woman as soon as the diagnosis is established. A delay of even a few days may mean a syphilitic child.
- 2 To be effective the drug must be spirillicidal. Intravenous neoarsphenamine and mapharsen have been most thoroughly tried. Penicillin alone or in combination with these may rapidly supplant the older types of therapy.
- 3 Protection of the child is the primary aim of treatment during pregnancy. No treatment should be used which is likely to be injurious to either mother or fetus. If necessary the syphilis may be cured in the mother after delivery.
- 4 Treat largely with spirillicidal drugs during the late months. The fetus is seldom infected prior to the twentieth week. Treatment may be largely with heavy metal in the arsenic bismuth regimen in the early months.
- 5 Reduce the initial dose of spirillicidal drug if treatment is begun after the fifth month. The first injection may be 0.2 gm of neoarsphenamine (or its equivalent), the average dosage for the first three weeks should not exceed 0.3 gm of neoarsphenamine per week. Total weekly dosage need never exceed 0.45 gm for the 150-pound adult. (For penicillin regimen see text.)
- 6 Continuous alternating is preferred to concurrent treatment if arsenic-bismuth regimens are used.
- 7 After the fifth lunar month the length of the bismuth course should not exceed four to six weeks, lest infection of the fetus result from lack of spirillicide.
- 8 Treatment should be continuous. No rest interval.
- 9 Arsenal should be given for four to six weeks immediately before delivery.
- 10 If reactions occur, stop treatment and reevaluate. Do not injure the mother with overzealous applications of treatment for the unborn child. The average pregnant woman tolerates normal antisyphilitic therapy well but, should reactions occur, they may be serious and should not be considered lightly.

* Modified from Stokes, Beerman and Ingraham, "Modern Clinical Syphilology," W B Saunders Company, 1944, p 1150, Fig 847

In the treatment of the syphilitic pregnant woman, the dosage of the arsenical need not exceed 0.45 gm of neoarsphenamine, or an equivalent amount of arsenoxide. Because of the conflicting results obtained by different observers with mapharsen, it is best to use it in dosage up to 0.05 gm every five days (Astrachan 1940,⁷ Minnich 1941,⁸ Castallo et al 1939,⁹ Soule and Bortnick 1943¹⁰). It is never too late to begin treatment for syphilis in pregnancy. A few treatments in the latter months of pregnancy may mean the difference between a syphilitic and nonsyphilitic baby. If there is any reasonable doubt that the mother is cured of her disease a syphilitic woman should be treated during every pregnancy, irrespective of the amount of treatment received previously and irrespective of the apparent clinic status. For many years the effective treatment of syphilis and the test of clinical cure has been such that this dictum has been essential and almost uniformly taught and followed. The apparent success of some of the more intensive methods of therapy in completely eradicating the syphilis from the patient leave serious doubt as to whether treatment is always necessary. It is still good practice, however to treat in each subsequent pregnancy if in doubt.

One of the more recent advances in the treatment of early acquired syphilis is *massive dose* chemotherapy with the arsenoxides (mapharsen, dichlorophenarsine hydrochloride) by the five day drip method or by a syringe technic and fever induced by typhoid vaccine. This has been tried in the pregnant woman and favorable reports, based on small numbers of cases of the efficacy of both methods have appeared (Sadusk and Shaffer 1942,¹¹ Benenson 1942,¹² Rattner 1943,¹³ Speiser, Wexler, Thomas and Asher 1945¹⁴). Speiser and his co-workers found that massive mapharsen therapy in the treatment of early infectious syphilis prior to the onset of pregnancy gave excellent results since there was only one failure among thirty-two patients so treated. We feel that these methods are not indicated because of the excellent results normally obtained with more conservative treatment and especially penicillin, as well as the increased risk to the mother (fatal encephalopathy, one case in forty-three patients treated, Speiser et al., 1945) when the more intensive methods are used.

CONTROL OF TREATMENT REACTIONS TO ARSENOTHERAPY

During pregnancy treatment for syphilis should be accompanied by exceedingly careful obstetrical prenatal care. Ingraham, Ingraham, Beerman, Spence, Arnold and Hassler¹⁵ have pointed out the value of having separate clinics for the pregnant syphilitic woman where these are practical. Pregnant women under treatment for syphilis should have weekly urinalyses and blood pressure determinations. Careful inquiry and inspection by a physician should be made to elicit any complaints from the patient which indicate circulatory embarrassment or kidney insufficiency. With careful attention to detail reactions to treatment

have been found to be infrequent and for the most part inconsequential. An extensive literature has accumulated on the subject of treatment reactions in syphilitic pregnant women, and a small number of deaths usually from acute hemorrhagic encephalopathy associated with arsenotherapy have been reported (Ingraham 1939,¹⁶ cf Moore 1939,¹⁷ Plass and Sacks, 1942,¹⁸ Kennedy and Hennington, 1943¹⁹)

It is difficult to set arbitrary rules to cover all complications of syphilotherapy when they arise. Individual case problems should be decided upon only after competent obstetrical and syphilologic consultation. One of the problems with acute hemorrhagic encephalopathy has been its simulation of the comas and convulsive states of the toxemias of pregnancy, and failure of recognition of the true situation until it was too late or until death had actually occurred. A constant awareness of this possibility is essential. We believe that, in general, treatment should be withheld until competent appraisal of the situation is possible under the following circumstances: (1) if the woman's blood pressure, which has been normal, increases to exceed 150/100, (2) if vaginal bleeding, hematuria, purpura or other hemorrhagic phenomena (hematopoietic injury) occur, (3) if there is jaundice or other evidence of liver damage, (4) if severe headache, visual disturbances or other evidence of central nervous system involvement become manifest (hemorrhagic encephalopathy), or (5) if the woman reports with a temperature of more than 100° F.

TREATMENT OF THE PREGNANT SYPHILITIC WOMAN WITH PENICILLIN*

If the preliminary results with penicillin in the prevention of congenital syphilis are borne out by our rapidly accumulating knowledge, this drug may supplant all others in the treatment of the syphilitic pregnant woman. Thus far, our information is limited to data collected from relatively small numbers of women, largely with symptomatic early syphilis whose infant offsprings have been followed for periods of a year or less postnatally. The bulk of the problem, namely the effect of penicillin on the pregnant woman with latent syphilis of unknown duration, remains largely an untouched field. On the other hand, the highest percentage of syphilitic babies come from women whose disease is of recent origin and it is a reasonable assumption that treatment which is effective in preventing the transmission of the infection in its severest form from mother to fetus will be equally effective in preventing the passage during the latent and late stages of the disease.

We would like first to present a case report, illustrating in detail the actual response of early syphilis in pregnancy to penicillin and then to discuss the present status of our knowledge of the use of this

* The work described in this section was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Pennsylvania.

drug to prevent congenital syphilis. This case was presented in part (Case No 13) in our original article on 'Penicillin in the Prevention and Treatment of Congenital Syphilis,'²⁰ but considerably more data have been collected since this publication and the woman has gone through another pregnancy.

Secondary Syphilis with Pregnancy Treated with Penicillin Second Pregnancy One Year Later without Treatment Both Children Normal—M. S., a Negress, 29 years of age, was in the sixth lunar month of her fourth pregnancy when she reported to the prenatal clinic of the Philadelphia General Hospital December 15, 1943 with secondary syphilis. Two previous pregnancies in 1940 and 1942 re-

RESULTS FOLLOWING PENICILLIN THERAPY IN SECONDARY SYPHILIS WITH PREGNANCY

Days Post Penicillin	Mother's Serologic Test in Kline Units	Days after Delivery	Serologic Test, Kline Units	Clinical Notes

spectively had been delivered by cesarean section because of cephalopelvic disproportion. A third pregnancy resulted in an abortion in February 1943. The exact duration of her syphilis was unknown, but her presenting symptoms consisted of a maculo-papular eruption scattered over the thorax and extremities, split papules at the angles of her mouth and numerous small condylomata lata.

on the vulva which revealed numerous *Spirochaeta pallida* to darkfield examination. It was assumed that her infection was acquired in the early months of the pregnancy and was not more than of two or three months' duration. She was admitted to the Hospital of the University of Pennsylvania on December 15, and started on treatment with sodium penicillin 25,000 Oxford units every four hours intramuscularly at 8:30 A.M. on December 16. The drug was dissolved in 2 cc of distilled water for administration. The course from then on is shown in the accompanying outline.

The method of treating the syphilitic pregnant woman with penicillin has been borrowed largely from published experience with the treatment of early syphilis in the adult.¹ The material about to be presented in the discussion represents the studies of the Syphilis Penicillin Panel of the Hospital of the University of Pennsylvania with forty-nine syphilitic pregnancies treated with penicillin between November 19, 1943 and May 26, 1945.

The initial clinical response seen in the case presented is similar to that found in the treatment of all patients with early syphilis with penicillin. *Spirochaeta pallida* is seldom demonstrable in the open lesion for longer than twelve hours after the institution of treatment and the lesions themselves are ordinarily completely healed before treatment is completed (i.e., within a one week period). This patient exhibited a moderate febrile Herxheimer reaction, her temperature fluctuating between 99° F and 101° F for the second and third day of treatment. This is likewise an almost uniform occurrence in pregnant women with early syphilis as with all cases of freshly acquired syphilis treated with penicillin.

The therapeutic shock at the commencement of treatment in the pregnant woman with early syphilis may occasionally, in our experience, be harmful to the fetus. Accompanying the febrile reaction a large percentage of our cases have had abdominal pain, gastrointestinal disturbances and in an occasional instance, symptoms of threatened abortion, with lower abdominal cramps and vaginal bleeding. One of the women in this series miscarried during the course of treatment and in another instance it was necessary to stop the treatment entirely and to continue therapy some weeks later after symptoms of threatened miscarriage had subsided. These various occurrences, though certainly not a contraindication to the treatment of the syphilitic pregnant woman with penicillin, have made us feel that reduction of the initial dosage is desirable for at least the first forty-eight hours. The dosage should be reduced by approximately three-fourths for the first day of treatment and by one-half for the next day, to be continued in full dosage on the third or fourth days and for the remainder of the course. We have not seen any complications from penicillin occurring in the latter half of the penicillin course.

Our experience would indicate that a total dosage of either 12 million or of 24 million Oxford units of sodium penicillin is satis-

factory both to prevent infection of the fetus and to cure the disease in the mother. This total dosage is preferably given in individual injections intramuscularly of 20 000 units (for 1.2 million unit courses) or of 40,000 units (for 2.4 million unit courses), every three hours. Specifically, if a 2.4 million unit total dosage were decided upon and the individual doses were reduced during the first forty-eight hours, the woman would then receive

- 10,000 Oxford units sodium penicillin intramuscularly every three hours for 8 doses, followed by
- 20,000 Oxford units sodium penicillin intramuscularly every three hours for 8 doses, followed by
- 40,000 Oxford units sodium penicillin intramuscularly every three hours for 54 doses.

The total treatment course would occupy from eight to nine days. If it were desired to shorten the course then dosage per injection on the last day or two could be increased. We, however, prefer the longer course and the higher dosage (i.e., 2.4 million Oxford units) since we believe that the pregnant syphilitic woman should be given every possible chance to give birth to a healthy child and that there should not be unnecessary risks resulting from reduced dosage or foreshortened courses. The only penicillin failure we have experienced thus far in the sense that the infant was infected in treating a woman with early syphilis, has been in a patient who received 1.2 million Oxford units of sodium penicillin in a period of four days. This mother had the combined disadvantage of the lower dosage and the shorter interval of treatment. She was not cured of her syphilis, relapsed infectiously, and transmitted the disease to her infant at about the time of delivery.

The above data indicate the degree of success we have had thus far with the treatment of the pregnant syphilitic woman to prevent congenital syphilis. Twenty-seven of the women treated have thus far been delivered and their babies have been followed for periods of two months to more than a year postnatally. Repeated physical examinations, blood serologic tests and roentgenograms of the long bones have failed to reveal evidence of syphilis in any except the one case above mentioned. These results, in the neighborhood of 95 per cent satisfactory, are at least as good, in fact, better than the average obtained with other modes of treatment.

It will be noted in the case report that the patient was still seropositive at term. A negative blood serologic reaction for syphilis by the time of delivery is not essential to the birth of a healthy infant. In fact, in only seven instances, among the forty pregnant women in our series who have thus far been carried through to term, was the mother's blood negative at the time of birth of her child. Thirty-eight per cent of our apparently healthy infants also had positive cord and neonatal Wassermanns. These uniformly reverted to negative in most instances by the age of three or four weeks so that they apparently

represented a transfer of syphilis reagin from mother to child rather than infection of the fetus

Whether penicillin will traverse the placental barrier and cure an already infected fetus is still a matter for speculation. Penicillin has been shown to permeate the placenta at term and has been recovered from the newborn infant when the mother has been treated during labor.²²

Of more interest from our standpoint, however, is the question of permeation of the placenta from the fourth to the ninth lunar months, since the fetus may be infected at any time during this period and since previous studies have shown that the permeability of the placenta is not uniform throughout the pregnancy. Some of our women have been treated prior to the sixteenth week, the majority between the sixteenth and thirty-second week, but a few later than the thirty-second week, all with uniformly good results. This suggests clinically that penicillin may readily permeate the placenta during all the latter months of the pregnancy though we cannot be certain of this point without a considerably longer period of study.

The fact of greatest interest, perhaps, in the case reported is that the patient has completed a second pregnancy, approximately sixteen months after receiving her course of penicillin for early syphilis and that preliminary investigation of the infant at least, covering a period of twelve weeks postnatally, indicates that he is normal. If a single course of penicillin will cure syphilis to the extent that we may disregard the long-established and much reiterated dictum of re-treatment in every pregnancy once syphilis is established, we will have made a great step forward in the management of the syphilitic mother. It will take many more cases to establish this fact, but the present instance is at least very encouraging.

EVALUATION OF THE EFFECTIVENESS OF TREATMENT IN THE SYPHILITIC PREGNANT WOMAN

In the last analysis, the effectiveness of antisyphilitic treatment of the pregnant woman is indicated by the presence or absence of syphilis in the newborn or the lack of adverse effect of antenatal treatment on fetal mortality. The consensus of recent contributions to this latter problem is that no definite fetal mortality rate could be associated with adequate antenatal therapy for syphilis.²³ With regard to diagnosis of syphilis in the newborn, most recent studies agree that the cord blood has little true diagnostic value, and cannot be depended on to decide whether or not the offspring of the syphilitic mother is infected. It may contain syphilis reagin and give a positive serologic test in the normal infant of a seropositive syphilitic mother, it may be negative even though the infant is diseased. This circumstance is not peculiar to the cord blood, but is equally true of the infant's blood during the

neonatal period. The cord or neonatal blood test result on the newborn is of value largely as a baseline for future determinations. As the result of a survey of the literature and numerous personal observations, we believe the offspring of the syphilitic mother may be considered to be infected when

- 1 *Spirochaeta pallida* is demonstrated in skin or mucous membrane lesions or in scrapings from the umbilical vein (Ingraham ⁴)
- 2 The blood serologic reactions of the tests for syphilis are strongly positive on repetition after the third month of life. Prior to the third month, in the absence of clinical symptoms it is difficult to establish a definite diagnosis without a knowledge of the mother's and infant's serologic reactions at birth and without the use of quantitative titrated tests. If such information is available then the following additional criteria for diagnosis are applicable in determining infection of the infant.
 - (a) The titer of the blood serologic reactions of the newborn child is significantly greater than that of the mother (or positive when the mother's reactions are negative)
 - (b) The titer of the infant's blood serologic reactions rapidly increases after birth (or reactions negative at birth subsequently develop a sustained positivity)
- 3 A properly interpreted roentgenogram of the long bones in a sero-positive infant during the first eight weeks of life which shows an unquestionable (preferably advancing) osteochondritis with or without periostitis (Ingraham, Shaffer, Spence and Gordon 1941²³)

SUMMARY

Congenital syphilis can all but completely be prevented by treatment of the syphilitic pregnant woman. The detection of syphilis in the pregnant woman is not always easy because of the meagerness of the symptomatology of the disease during pregnancy and because of the failure, at times, of the physician to use every available resource at his command. Since infection of the fetus may occur prior to the fifth lunar month of pregnancy, the earlier diagnosis of syphilis in the mother is made, the more chance the infant has of escaping infection, provided treatment is instituted as soon as the disease is discovered.

Almost all syphilis in pregnancy is discovered by the routine use of the blood serologic tests. A test early in pregnancy will detect ante-conceptionally acquired syphilis but a repetition of the test made near the time of delivery (seventh to eighth month) will be necessary to detect infections occurring during the early months of pregnancy. While occasionally there may be false positive reactions in the blood in pregnancy there is just as much likelihood of false negative reactions. On the whole, the blood tests are just as reliable in pregnancy as in other phases of syphilis. New methods of blood serologic

(Kahn verification test, etc.) have not eliminated the distrust felt by some in blood tests during pregnancy

Other aids in diagnosis of syphilis in pregnancy are the careful history and physical examination. These procedures are especially necessary in cases of seronegative syphilis in pregnant women. For practical purposes of diagnosis, it is recommended that blood tests be made routinely on every pregnant woman early in the pregnancy and that, if they are negative, they be repeated later (at term, if not in the last months of the pregnancy).

If syphilis is discovered in the pregnant woman, the possibility of the fetus becoming infected depends on several factors. The more recent the infection in the mother, the more liable is the child to be syphilitic. The child born of a syphilitic mother with a negative blood serologic test is less apt to be infected with syphilis than is one born of a seropositive mother. The amount and kind of prenatal therapy and the time at which it is instituted in the pregnant woman are factors of the utmost importance in the question of transmission of syphilis from the mother to her offspring. Treatment begun at or about the fourth month of pregnancy and continuing at weekly intervals to total not less than 4 gm of arsenical (neoarsphenamine) or the equivalent of arsenoxide with or without heavy metal (bismuth subsalicylate) constitutes about optimal conditions for the prevention of prenatal syphilis.

This type of treatment may be supplanted, in early acquired infections at least, by 2.4 million Oxford units of sodium penicillin intramuscularly given in individual dosage of approximately 40,000 units each every three hours over an interval of from eight to nine days. Preliminary results with limited numbers of cases indicate a degree of success with this type of treatment at least equal to that obtained from the arsenical bismuth regimens. The mother is moreover apparently cured of her disease by this single short course of therapy.

Pregnant women tolerate arsenical and heavy metal treatment well. One must not overlook the fact, however, that these individuals do occasionally show serious reactions to the arsenicals, and treatment should be adjusted accordingly. A urine examination and blood pressure determination before each arsenical injection are of the utmost importance. The aim of treatment is not to cure syphilis in the pregnant woman but to prevent syphilis in the offspring. From this point of view, syphilis in pregnancy is early syphilis and the drugs most effective in early syphilis are the strongly spirillicidal drugs. The arsenicals, neoarsphenamine (0.45 to 0.6 gm at weekly intervals), mapharsen (0.04 to 0.06 gm at five day intervals) or penicillin (for exact dosage see body of paper) may be used in accordance with the physician's convenience. Bismuth subsalicylate in dosage of 0.2 gm (about 120 mg of metallic bismuth) is the heavy metal of choice where it is desirable to use this type of drug. In the arsenic-bismuth regimen,

treatment should be alternating and continuous and it should be so arranged that the predelivery therapy be arsenical. If treatment is begun after the fifth month, it should start with an arsenical. In case of reaction, treatment should be individualized.

Examination of the cerebrospinal fluid wherever necessary should be deferred until after delivery. In all of our services the test is made just before discharge from the maternity hospital.

The newer intensive methods of chemotherapy (five day continuous intravenous drip and syringe technic employing multiple injections) have not had adequate trial in the treatment of the pregnant woman and the dangers of toxicity are not fully worked out.

PREGNANCY IN DIABETES

ROSS B WILSON, M.D *

PREGNANCY in diabetic patients has in the past caused great concern because of the complications innate in all diabetic patients plus the added hazards due to or accentuated by pregnancy. In the preinsulin era the mortality among pregnant diabetics was unquestionably higher than the average. The advent of insulin has reduced this mortality and solved some but by no means all of the problems encountered in the management of pregnant diabetic patients. Complications still attend simple diabetes and these plus the common hazards of pregnancy and childbirth result in an exacerbation or increased frequency of accidents.

MATERNAL ASPECTS

It is not the purpose of this paper to enter into a detailed discussion of the management of diabetes per se, but to discuss some of the problems peculiar to the pregnant diabetic. It is generally conceded that in pregnancy standardization of the diabetic condition is more difficult than in uncomplicated diabetes. The fluctuation of blood sugar levels in the different phases of gestation as a result of metabolic changes incident to pregnancy and the probable effect of the fetal pancreatic secretion are well recognized in earlier writings. As a result of the many factors involved it is far more imperative that the pregnant diabetic patient have more rigid supervision by a physician capably trained in the treatment of diabetes than a nonpregnant diabetic. Close correlation of the medical and obstetrical care of these patients must be emphasized.

Fluctuation of the blood sugar levels and the varying insulin and carbohydrate requirements in the different phases of pregnancy have been pointed out. There is reason to doubt that the fetal pancreas plays a significant role in this occurrence. Frequent laboratory studies, especially urinalysis and blood sugar determination, are imperative. Urinalysis and adjustment of insulin dosage by the patient are not sufficient. Suffice to say, that the medical management of the pregnant diabetic be such that by diet regulation and if necessary insulin administration there is maintained a carbohydrate intake adequate for the pregnancy and at the same time one that maintains a blood sugar level that approximates the normal and does not create a demand on the fetal pancreas to make up a deficiency on the part of the maternal pancreatic function.

* Instructor in Obstetrics, Jefferson Medical College; Chief, Obstetric Service, Lankenau Hospital; Obstetrician and Gynecologist, Philadelphia Lying In Hospital.

It is Allen's opinion that since the introduction of insulin the maternal mortality in pregnant diabetics has been lowered to the average of that in pregnancy uncomplicated by diabetes. At the Philadelphia Lying-In Hospital only one maternal death occurred in a total of forty-one deliveries (since 1938) in patients with diabetes. This death took place in a patient, Para VIII, as a result of a rupture of the uterus during the delivery of a breech presentation after a labor of nine hours and forty-three minutes. The infant weighed 9 pounds 6¾ ounces. There had been adequate control of her diabetic condition during this pregnancy and the maternal death was not attributed in any way to the diabetes. Considering the problem from a maternal point of view, numerous investigators have however indicated an increased incidence of *toxemia* in pregnant diabetic patients and a tendency to the production of large babies, suggesting, at least, the likelihood of difficulties due to dystocia as a result of disproportion. In the cases reviewed since 1938 at the Philadelphia Lying-In Hospital, eighteen of the forty-one deliveries resulted in babies whose weight was 8 pounds or over. There was maternal toxemia in thirteen of this group. Miller and co-workers² found that a birth weight of 11 pounds or more was eighty times as frequent in infants of diabetics as in infants of nondiabetic women. Bill and Posey³ found that nine infants out of forty-four born to diabetic patients weighed 9 pounds or over. In a series of thirty-one pregnancies occurring in twenty-three diabetic patients reviewed by Laviates⁴ and co-workers, maternal toxemia was present in ten. There were four cases of hypertensive disease and six of preeclampsia. Bill and Posey³ found twelve cases of preeclampsia in forty-four diabetic pregnant women. Allen¹ estimated that approximately 70 per cent of a series of patients studied by him had one or all of the cardinal signs of toxemia. Priscilla White⁵ likewise found a high percentage of maternal toxemia in patients studied by her.

Conceding the tendency of increased incidence of toxemia in diabetes of pregnancy, the question presents itself as to why this occurs and how best it can be prevented. It is doubtful whether it can be completely clarified until the entire problem of toxemia in pregnancy is solved. At the present time, the incidence of toxemia of pregnancy in the nondiabetic has been lowered by rigid prenatal supervision entailing dietary and fluid balance and elimination regulation. However, toxemias still occur. White⁵ has produced evidence to support the idea that in diabetic patients at least the toxemia is due to hormonal disturbance or imbalance. She and her co-workers studied 118 pregnant diabetic women by hormone assays for chorionic gonadotropin and pregnandiol. Of the 118 patients studied she found that forty-one had normal hormone levels. Only 2 per cent of these patients showed toxemia of pregnancy. Of the remaining patients who showed abnormal levels there were twenty-seven that were not treated by hormone therapy. Fifty-two per cent of these showed evidence of toxemia or

premature delivery The remaining fifty-seven patients treated showed a much lower incidence of toxemia.

The problem of *dystocia* due to large babies has not been entirely solved by diabetic control or hormonal medication. Careful evaluation of fetal size by physical examination and the use of competent x-ray examination of the maternal pelvis and of the fetal skeleton, and the proper selection of method of delivery are of paramount importance in a pregnant diabetic.

FETAL AND NEONATAL ASPECTS

The reports from investigators in recent years have dealt largely with fetal aspects of this problem. As mentioned above, the maternal mortality has been lowered to that of the average prenatal case uncomplicated by diabetes. However, the fetal death rate has not been greatly lowered. It is still enormously high. Laviertes and associates⁴ reported twelve fetal deaths in thirty-one deliveries. Miller and associates² stated that the fetal mortality rate was five times higher in diabetic than in normal pregnancy cases. Bill and Posey³ studied forty-four diabetic patients and found that twelve of their infants were either stillborn or died soon after birth. Lawrence and Oakley⁵ reported a study of fifty-four pregnancies in forty-four diabetic patients, the total number of babies was fifty-seven with a fetal mortality of 33 per cent. His studies indicated some relationship between fetal death rate and *proper supervision of the maternal diabetes*. He divided the supervision of the maternal diabetes into three groups, those that have none, those that have partial supervision, and those which were completely studied and supervised. A mortality of 70 per cent occurred in babies born of mothers with uncontrolled diabetes. When partial supervision was instituted, a mortality of 60 per cent occurred. In those with complete supervision it was lowered to 23 per cent. Allen,¹ however, reported that insulin accomplished relatively little in the lowering of fetal death rate. In the total number of forty-one deliveries at the Philadelphia Lying-In Hospital, in the series mentioned, there were five dead babies. Three of these occurred in patients that had had inadequate diabetic supervision. Two occurred in those considered adequate.

The chief causes of the high rate of fetal mortality has been generally conceded to be gigantism, causing dystocia and difficult delivery, as mentioned above, prematurity, independent of or associated with toxemia of pregnancy in the mother, intrauterine fetal death occurring most frequently in the last few weeks of pregnancy, and neonatal death associated with hyperinsulinism of the fetus.

In the preinsulin era the cause of large babies was thought to be the maternal hyperglycemia, but since today the incidence of large babies still remains high in spite of the widespread use of insulin, as has been pointed out, some other cause of this condition in the new-

born must be sought Bill and Posey³ quote Snyder and Hoopes' work in which they produced overdeveloped offspring of animals by injection of prolactin as the beginning of the support of this idea White's⁵ work definitely supports the hormonal origin of the condition

Prematurity has long been considered by obstetricians and pediatricians as one of the chief causes of fetal mortality Although many factors may be involved in the cause of prematurity, in the experience of the average obstetrician engaged in the care of prenatal patients it very frequently results from, or is associated with, some form of the toxemias Since there seems to be a high incidence of toxemia in diabetic patients, we should therefore expect a corresponding increase in fetal death rate due to prematurity and immaturity In forty-one cases studied by White,⁵ in which she considered the normal gonadotropin and pregnandiol hormone assays as normal, no premature births occurred In this group there was only a 2 per cent incidence of toxemia, and the fetal mortality was 5 per cent In the abnormal levels, not treated by hormonal therapy, there was 52 per cent incidence of toxemia and premature delivery in the twenty-seven cases The fetal mortality in this group was 40 per cent In fifty-seven abnormal patients treated by hormones, prematurity occurred in 25 per cent and toxemia was definitely modified The fetal survival in this group in spite of the prematurity was 92 per cent

There are still those *unexplained instances* in which intrauterine fetal death occurs in late pregnancy or in the early stages of labor This seems to be most frequent in the last three or four weeks of gestation The theory that death is caused by some abnormal hormonal activity cannot be discarded It is in such instances that termination of the pregnancy by cesarean section three to four weeks before term is indicated At the Philadelphia Lying-In Hospital, in the forty-one deliveries of diabetics, five stillbirths occurred Three were attributed to intrauterine death before labor, and the remaining two were due to placenta praevia and difficulty in extracting the body at time of delivery

Neonatal deaths due to *hyperinsulinism* have occurred, but by proper management can be avoided By the administration of glucose by mouth or the parenteral route with proper laboratory studies of the blood sugar level of the infant, the danger of fetal death in these instances can be almost completely eliminated As soon as the infant has established regular feedings this danger has usually passed

METHOD OF DELIVERY

The method of delivery of diabetic patients has been the subject of much discussion In the preinsulin era all operative procedures in diabetic patients were wisely avoided whenever possible Cesarean section was especially hazardous Today with insulin the operative risk

in diabetics has greatly decreased and cesarean section is common. This tendency to resort to cesarean section is due no doubt to a desire to save babies that formerly died in utero during the last weeks of gestation, and because of the high incidence of large babies. Many, however, advocate vaginal deliveries as the routine method except in the presence of purely obstetrical indications for cesarean section such as disproportion and placenta praevia. Bill and Posey³ reported thirty of forty-four diabetic patients were delivered vaginally, while fourteen had cesarean sections. Four of these were for causes other than those associated purely with diabetes. At the Philadelphia Lying-In Hospital nine of forty-one babies were delivered by cesarean section. Certainly, when obstetrical indication for cesarean section exists the operation should not be avoided in a well controlled diabetic.

SUPPORTIVE THERAPY ANALGESIA AND ANESTHESIA

During labor and delivery and during the immediate postpartum period, special care of the diabetic picture should be exercised. Too often as a result of lack of proper food and fluid intake due to loss of desire for food, or routine restriction of oral intake as a preparation for anesthesia and operation, or ill advised use of analgesics which prevent the oral administration of nourishment, a disturbance of glucose metabolism occurs. This can be avoided by the proper selection of analgesia and anesthesia and the use of a parenteral fluid, such as glucose solution and insulin, when indicated. The requirements of these different procedures are determined by frequent laboratory studies.

The choice of agents for analgesia and anesthesia is much wider when the diabetic phase is well regulated. In many instances spinal anesthesia and local infiltration have been avoided, but in our opinion, since we are able by competent medical supervision to maintain a safe balance in the metabolism of the patient, the use of local and regional anesthetics is not only permissible but definitely indicated. They result in less disturbance of oral intake and of fluid balance as a result of vomiting due to the anesthetic agent, and have been used by us without harmful results. There seems to be no contraindication to the use of caudal anesthesia, in fact, its employment seems to be definitely indicated since it can be used during the progress of labor as well as delivery, whether it be by the vaginal route or by cesarean section, and yet not interfere with the routine administration of fluid and food by the oral route, obviating, to some extent at least, the necessity for intravenous therapy. From the fetal aspect the use of a spinal, caudal or local anesthetic is desirable because they have no effect whatever upon the offspring. With their use the premature or otherwise abnormal baby has a far better chance for survival than when the usual inhalation anesthetics and analgesics are employed.

PUERPERAL INFECTION, ITS PREVENTION AND TREATMENT

MAHLON C. HINEBAUGH, JR., M.D.*

THE development of specific chemotherapeutic agents and antibiotics during the past ten years has materially changed the treatment of puerperal infection, and fortunately has brought about a decided improvement in maternal mortality. Despite the proven value of the sulfonamides, penicillin and more recently streptomycin† in combating infections generally, it must be remembered that puerperal sepsis is protean in its manifestations. It is rare to find a single causative organism. Generally we are dealing with a mixed infection in which symbiosis tends to increase the virulence. It is for this reason that treatment is frequently disappointing. Despite the shortcomings of specific therapies, they have come to be regarded as panaceas. It is well to sound a note of warning to the profession generally lest we be lulled into a false sense of security and overlook the fact that prevention transcends all other measures as the treatment for puerperal infection.

PREVENTION

The prophylaxis against puerperal infection may be divided into (1) antepartum, (2) intrapartum and (3) postpartum care. *Antepartum* prevention should begin with the patient's first prenatal visit. In addition to an evaluation of the general state of health, careful search should be made for possible foci of infection and adequate treatment for their removal instituted. Detailed instruction should be given in the matter of local cleanliness, tub baths and sexual intercourse are strictly forbidden during the latter months. In addition to supervision of the diet to insure good nutrition, secondary anemia should be combated by the use of iron, vitamin B, and liver extract. These measures are designed to maintain a high standard of general health in preparation for labor.

Intrapartum Care—Upon admission, unless delivery is imminent, the patient should be given a shower or sponge bath before admission to the labor room. Strict care should be exercised in preparation of the

*Diplomate, American Board of Obstetrics and Gynecology. Demonstrator of Obstetrics, Jefferson Medical College. Assistant Obstetrician, Jefferson Medical College Hospital, Philadelphia.

†This new antibiotic is at the present time under clinical investigation. It holds promise of being a specific in the treatment of infections caused by certain gram-negative bacteria, notably *Endamoeba coli*, *Eberthella typhosa*, and *Friedlander's bacillus*. To date, we have employed it in only one case. Further trial will be necessary in order to determine its value in the treatment of puerperal infection.

genitalia to avoid contamination of the vagina. This is especially true in multipara in whom the vulva gapes. It is advisable to give a cleansing enema if sufficient time permits in order to prevent contamination with feces during the delivery. If membranes have prematurely ruptured 1 ounce of a suitable antiseptic, such as zephuran chloride 1:1000, should be instilled into the vagina every four to six hours. In order to determine the progress of labor, rectal examinations are to be preferred. It must be emphasized that these should not be carried out indiscriminately. Vaginal examination should be reserved for a definite indication. Careful preparation of the patient and the obstetrician must precede their performance.

The delivery should be conducted under the most rigid aseptic technique. Meddlesome interference as by manual dilatation of the cervix, premature application of forceps or elective internal podalic version is to be condemned and serves only to increase the danger of infection. On the other hand, prophylactic forceps combined with episiotomy are advantageous and are much safer than permitting a head to pound for hours against a rigid perineum. If it becomes necessary to enter the uterus, extreme caution is urged and the examining hand should be liberally washed with a suitable antiseptic solution to prevent carrying infective organisms from the vulva or rectum into the uterine cavity. Also, following any intrauterine manipulation the uterus should be thoroughly explored for possible rupture. The third stage of labor should be allowed to proceed normally. Undue haste in the removal of the placenta predisposes to hemorrhage, lowered resistance and subsequent infection. Manual removal of the placenta should be restricted to those cases in which either hemorrhage, retention or adherence is endangering the patient's life and welfare. The placenta should be carefully inspected in order to make certain it has been completely expelled. The retention of even a small fragment may result in serious infection. Lacerations of the cervix, vagina, pelvic floor and perineum should be immediately repaired under proper surgical technique.

Postpartum prophylaxis is essentially dependent upon the strict observance of a high standard of nursing care. As soon as the patient has reacted from her labor and delivery she should be placed in the White position (commonly called Fowler). This affords freedom for lochial discharge. The use of one of the ergot derivatives is advised in order to maintain a firmly contracted uterus, thus keeping the uterine sinuses closed. Distention of the bladder should be prevented. In addition to the danger of urinary tract infection and its possible extension to the genital tract, there is mechanical interference with uterine discharge. If at any time during the puerperal period a patient becomes febrile, immediate isolation should be carried out. The need for adequate isolation facilities in any well organized maternity cannot be emphasized too strongly. These should include labor and de-

livery rooms for the potentially or actually infected case, and a well ventilated ward for their puerperal care. The staff in attendance must be completely separated from contact with clean cases

TREATMENT

Any discussion of the active treatment of infection once established is dependent upon a knowledge of the pathology. To state it simply, the pathology of puerperal infection is that of wound infection generally. The parturient canal is always a wound surface whose extent is dependent upon the following factors: (1) the placental site and endometrial surface, (2) lacerations of the uterine body and cervix, (3)

Fig 185—Areas of extension of puerperal infection.

contusions or lacerations of the vaginal vault, vulva or perineum. Fortunately the infection remains local in the majority of cases. Extension occurs by way of the lymphatics (primarily), the venous system, continuity of surfaces or by a combination of all. The accompanying diagrammatic sketch (Fig 185) serves to illustrate these routes of extension.

Although the therapeutic measures instituted in the management of puerperal infection will be separated into the various clinical types, it must not be overlooked that such simplification does not always exist clinically and frequently a combination is present.

Vulvitis and Vaginitis.—These types of infection most commonly occur as a result of a break in technic during the repair of an episiot-

omy or perineal laceration and is characterized by local pain, edema and redness

Treatment for this condition consists in immediate removal of sutures to afford adequate drainage and local application of heat in the form of moist sulfanilamide compresses. The external genitalia should be frequently bathed with a mild antiseptic solution, but intravaginal douches are expressly contraindicated because of the danger of carrying infection higher up. Prompt recognition and early institution of the above named measures will bring about an early subsidence of the infection and is the best means of preventing extension.

Endometritis (Sapremia)—Endometritis occurs more frequently than any other type of puerperal infection. Indeed, it is doubtful if infection exists without some involvement of the endometrial surface. Fortunately in most instances it remains a localized process. It usually starts about the third or fourth day postpartum, is characterized by malaise, fever, pain referable to the uterus, subinvolution and a profuse foul lochia. Formerly the diagnosis was based purely on the clinical symptoms and signs and treatment was essentially symptomatic. The patient was placed in a semisitting position, a soft diet was given, fluid intake was increased and elimination was maintained by mild laxatives or simple enemas. In an attempt to maintain a firmly contracted uterus an ice bag was placed on the abdomen and ergot derivatives were administered. Under this regimen infection usually subsided in a week to ten days with complete recovery.

The present method of treatment is dependent upon a bacteriologic diagnosis in addition to the clinical findings. This may be determined by lochial or uterine culture. The technic is as follows:

The patient is placed on a bed pan and the external genitalia are carefully cleansed with lysol solution or other suitable antiseptic. Using sterile gloves and instruments the physician gently inserts a bivalve speculum into the vagina, exposing the cervix. All lochial discharge is wiped away from the exposed cervix and vaginal fornices. A sterile glass pipette with suction bulb attached is then carried into the uterine cavity, care being taken not to allow the pipette to brush the vaginal mucous membrane, thus causing contamination. The material thus obtained is immediately cultured for both aerobes and anaerobes. The value of anaerobic culture cannot be emphasized too strongly for the anaerobic streptococcus is frequently found as a causative agent and the recovery of *Clostridium welchii* is by no means rare. A laboratory report is requested at the end of twenty-four hours to avoid delay in the institution of treatment.

The plan of specific therapy is dependent upon the type and number of organisms recovered in the culture. Of these, *Streptococcus pyogenes* is most common. Penicillin is the best therapeutic agent when infection is due to the staphylococcus, *Streptococcus pyogenes*, *Streptococcus haemolyticus*, *Streptococcus anaerobius*, gonococcus and *Clostridium welchii*. The dosage and method of administration are dependent upon the type and severity of the infection. The pri-

major object in every case is to bring the infection under control as quickly as possible. The plan adopted in our clinic is as follows. Injections are given intramuscularly, the initial dose being 20,000 units. Subsequent doses of 10,000 units each are administered every three hours making a total of 90,000 units during each twenty-four hour period. Treatment is continued until the temperature has remained normal for forty-eight hours. The penicillin is then stopped and the patient's subsequent course carefully followed. In all infections caused by the *Streptococcus hemolyticus* the initial injection is given intravenously.

Penicillin is contraindicated because it is ineffective if infection is due to *E. coli*, *B. proteus*, *B. pyocyaneus* or Friedländer's bacillus. In all cases in which infection is due to these gram-negative bacteria sulfonamides are used. We have found sulfadiazine to be most effective and it is generally well tolerated by the patient. It is administered orally, the initial dose being 2 gm followed by 1 gm every four hours. The drug is discontinued after the temperature has returned to normal. An alkali, such as sodium bicarbonate, grains 15, is administered with each dose of sulfadiazine. Blood levels of 8 to 12 mg are suggested for optimum results. These determinations are advised every forty-eight hours. Frequent blood counts should be made in view of the tendency of the drug to cause anemia and leukopenia. The urine is examined daily for the appearance of sulfadiazine crystals or any evidence of renal damage. Should this or any other toxic manifestation occur during the course of treatment the drug is stopped immediately.

Of no less importance than the specific measures discussed in the preceding paragraphs are the prevention and intensive treatment of secondary anemia. Although no arbitrary rule can be made, we routinely transfuse all patients whose hemoglobin is below 70 per cent and erythrocytes less than 3,500,000. Generally repeated small transfusions (250 cc. of whole citrated blood every second day) are more effective than one or two large transfusions. In addition, the patient is given large amounts of vitamin B complex, vitamin C, liver extract and iron.

A comparison of the results obtained with the older and the present methods of treatment leaves no doubt as to the superiority of the latter. In our experience the response has been prompt and in many instances dramatic. The patient's temperature generally returns to normal within forty-eight to seventy-two hours and all local signs of infection have disappeared. In addition to the proven value of specific therapy in combating endometritis, it has in our opinion greatly reduced the incidence of extension to the parametrium and peritoneal cavity.

Metritis.—Deep penetration of the uterus is most frequently seen when the causative agent, notably the hemolytic streptococcus or staphylococcus, is virulent and rapidly invasive, thus preventing the

formation of the defensive barrier which normally limits the infection to the endometrium. Clinically the differentiation between this infection and endometritis is often difficult. In some cases the symptoms and signs are the same, more commonly however, it manifests itself by increased intoxication, pain of greater severity and marked uterine tenderness. The lochia is essentially normal in quantity and there is no foul odor.

The management of this type of infection is essentially the same as for endometritis. As previously stated, the organisms most frequently encountered are the hemolytic streptococcus and the staphylococcus against which penicillin is particularly effective. An initial dose of 20,000 units is administered intravenously followed by 10,000 units intramuscularly every two hours or a total of 130,000 units during each twenty-four hours.

Pelvic Cellulitis (Parametritis)—Cellulitis is a not uncommon puerperal infection. In the majority of instances involvement is unilateral and is the result of invasion of the loose pelvic areolar tissue following lacerations of the cervix or lower uterine segment. In a certain percentage of cases the infection is secondary to endometritis and is caused by extension through the lymphatics of the broad ligaments. It usually starts at the base of the broad ligament and follows the planes of cleavage of the pelvic connective tissue. The inflammatory reaction is usually intense and early exudation occurs with the formation of a palpable mass. The location of the "tumor" is largely dependent upon the degree of involvement and the course which the exudate follows. Von Rosthorn has given us a useful classification of pelvic exudates based upon their origin and course of extension: (1) lateral horizontal exudates located in the base of the broad ligaments which spread to the bony pelvic wall and then anteriorly pointing above Poupart's ligament, (2) secondary extension from a previous endometritis through the lymphatics of the uterus (these exudates occur in the upper portion of the broad ligament near the uterine cornu and extend into the iliac fossae), (3) posterior exudates arising from the retrocervical tissues which extend into the rectovaginal septum, (4) anterior exudates arising from the precervical tissue which spread upward around the ureters to the abdominal wall.

Early diagnosis is difficult. Suspicion is aroused by pain and tenderness in either or both sides of the uterus without evidence of peritoneal involvement. Once tumor formation has occurred the diagnosis is easy. Without treatment one of two things may occur: (1) complete absorption without suppuration and (2) suppuration with subsequent abscess formation. When an abscess forms it may rupture spontaneously into a hollow viscus, the general peritoneal cavity, or externally through the skin, thus bringing about spontaneous cure. In a small percentage of cases the abscess becomes encapsulated, gradually shrinks in size but may remain for a period of years.

The treatment of pelvic cellulitis is directed toward limitation or extension of the process and the prevention of abscess formation. In addition to the routine measures which are carried out in all types of puerperal infection, the following plan has been adopted. At the earliest sign of infection a cervical culture is made in the hope of determining the causative organism. In most instances it is found to be *Streptococcus pyogenes*. Penicillin therapy is immediately instituted. If the infection is of moderate severity the dosage and administration is the same as that for the treatment of metritis. If on the other hand the degree of intoxication is profound, an initial dose of 20,000 units is administered intravenously, followed by constant intravenous injection of penicillin in normal saline. The drip is so regulated that 3000 units are delivered every hour. If the causative agent is found to be penicillin resistant, sulfadiazine is given. In order to establish a satisfactory blood level rapidly 5 gm. of the sodium salt is injected slowly intravenously, this is followed by the oral administration of 1 gm. every three or four hours. In cases in which the infection is of a mixed type a combination of penicillin and sulfadiazine may be used. The patient is carefully observed for any evidence of abscess formation. Should this occur an attitude of watchful waiting is adopted.

Interference is contraindicated until localization has taken place and the abscess has become completely walled off. Surgical treatment consists of incision and drainage of the abscess. The site of incision is dependent upon its location. If the abscess points above Poupart's ligament, a small incision is made just above and parallel to the ligament carefully dissecting each layer until the wall of the abscess is reached. A small opening is then made into the abscess cavity sufficient to permit its exploration by the finger to determine the extent of the abscess. The pus is evacuated and a drainage tube inserted. Great care must be exercised to avoid opening into the peritoneal cavity. A generalized and even fatal peritonitis might easily result from such a breach of technic. Whenever possible, abscesses should be drained through the vagina. Posterior abscesses are drained by simple incision into the rectovaginal septum. In some instances it is possible to drain lateral abscesses in this manner. This may be attempted if the lower limit of the abscess is at a level with the cervix. Incision is made posteriorly as near the midline as possible in order to avoid damage to either the ureter or uterine vessels. In the case of abdominal abscesses drainage is accomplished suprapubically. Following incision and drainage, healing takes place rapidly and prompt recovery is the rule.

We have found the use of x-ray of definite value in the treatment of this condition and employ it as an adjunct to specific therapy and surgery. Although the exact mode of beneficial effect is not known, it has in our experience materially helped to limit and subsequently localize the infection. It also tends to hasten healing following incision.

and drainage Small doses are used, 25 to 75 roentgens per treatment, the total dose not to exceed 500 roentgens.

Pelvic Peritonitis (Perimetritis)—Invasion of the perimetrium may occur secondary to many forms of local puerperal infection such as endometritis, pelvic cellulitis or a previously existing salpingitis Fortunately in most cases the invading organisms do not possess a high degree of virulence and the infection remains limited to the pelvic peritoneum Extension to the peritoneal cavity takes place (1) through the lymphatics of the uterus, (2) the blood vessels, (3) a combination of both, (4) rupture of an old pyosalpinx during labor and (5) by direct invasion following rupture or laceration of the upper uterine segment The pathologic findings in puerperal peritonitis are identical with those of surgical peritonitis The symptoms and signs vary with the mode in which infection reaches the peritoneum Extension through the lymphatics from a previous endometritis is the most common, in which case the onset is gradual and early recognition difficult In contrast, peritonitis which follows a ruptured pyosalpinx is abrupt in onset and is accompanied by severe pain, marked tenderness which rapidly spreads over the abdomen, and collapse We have seen three fulminating cases of peritonitis following this accident during spontaneous delivery In each instance the infection was so overwhelming that the patient succumbed within seventy-two hours The diagnosis of the cause was made at autopsy

Before the days of specific therapy the end result of treatment was at best unsatisfactory Under the present plan of management the patient is placed in Fowler position This affords postural drainage and tends to prevent ascension of the infection Vomiting is controlled and decompression accomplished by either the Wangenstein apparatus or a Miller-Abbott tube The passage of gas per rectum is facilitated by the insertion of a rectal tube Enemas should not be given Fluid intake is maintained by intravenous drip, 1500 to 3000 cc daily of 5 per cent glucose in normal saline Blood transfusions are routinely administered to combat anemia and increase the patient's resistance The predominant organisms which cause puerperal peritonitis are susceptible to penicillin It is administered by the intravenous route previously described under the treatment of severe pelvic cellulitis Because of the severity of the infection the dosage requirement is higher In addition to the 20,000 unit initial dose, the intravenous drip is regulated to deliver 5000 units during each hour Sulfadiazine may be used in conjunction with penicillin because of the inhibiting effect on the colon bacillus which is frequently found as a secondary invader The dosage and method of administration have been previously described

If the infection responds well to treatment, early resolution and absorption may be expected In certain instances, however, suppuration with subsequent abscess formation develops When this occurs, incision and drainage of the abscess cavity is indicated As in the case

of pelvic cellulitis, surgical interference is delayed until the abscess cavity has become walled off. Most commonly the collection may be found in the cul-de-sac, the operation for which is posterior colpotomy. The removal of infected tubes or ovaries should be delayed until after all evidence of acute infection has completely subsided. Failure to observe this precaution might readily be followed by a rapidly spreading or fatal generalized peritonitis.

X-ray therapy has proved to be of definite value in the treatment of these cases. The dosage is exactly the same as for pelvic cellulitis.

Bacteremia (Septicemia)—Bacteremia is the most serious type of infection which occurs during the puerperium. Prior to the development of specific therapy the death rate from this dreaded disease was extremely high and on a par with hemorrhage and toxemia. The most important single causative agent is the beta hemolytic streptococcus but the staphylococcus, anaerobic streptococcus and many other organisms may be found. Direct involvement of the blood stream may be gained by the lymphatics (most frequent), by the blood vessels or a combination of the two. The resultant clinical picture is largely dependent upon the mode of invasion and the virulence of the infecting microorganisms. A period of incubation which is somewhat variable precedes the actual outbreak of symptoms. During this time there may be evidence of the local infection from which the bacteria enter the blood stream. It is generally impossible to determine the exact time of invasion. Following this period of incubation, the characteristic syndrome of a serious bacteremia appears. There is a severe shaking chill lasting from five to thirty minutes during which the temperature rapidly rises and reaches 103° to 104° F. The pulse rate is increased out of proportion to the elevation of temperature. In addition there are the usual symptoms of profound intoxication and signs which point to extension of infection from its site of origin. The diagnosis is confirmed by positive blood culture. Early in the course of the disease there may be an insufficient number of bacteria in the blood stream to obtain a positive culture. Under such circumstances a clinical diagnosis must be relied upon. The organisms are most frequently recovered from the blood during the rigor when the temperature is rising and should be taken at this time. Cultures made after the chill has subsided and the temperature is receding are of little value. It is sometimes necessary to make repeated cultures before a positive one is obtained. In addition to the isolation of the causative micro-organism the determination of the number of colonies per cubic centimeter of blood is of considerable prognostic value.

At the present time treatment for puerperal bacteremia is largely preventive. When early recognition and active treatment of local infection is properly carried out, blood stream infections will almost invariably be prevented. Penicillin is by far the best therapeutic agent and should be given intravenously. The dosage and administration have

been previously described under the treatment of peritonitis. We believe that repeated small blood transfusions are equally as important as specific therapy.

Pyemia (Metastatic Bacteremia).—Pyemia is a term used to describe a more chronic form of septic infection. It is usually secondary to local uterine infection in which venous thrombosis has occurred. Small pieces of infected thrombi break loose to form emboli which are carried through the blood stream to distant parts, thus causing metastatic pus formation. The treatment for this condition combines the specific measures employed in bacteremia, and the incision and drainage of local abscesses which form.

Thrombophlebitis.—Infection of the veins with thrombus formation may occur as the result of severe trauma during delivery or in association with local infection. Frequently the infection begins in the uterus as a local thrombophlebitis, then extends by way of the pelvic veins through the common iliacs either upward into the vena cava or downward through the external iliac into the femoral veins. The infection is of two types, suppurative and nonsuppurative. In the suppurative form embolic phenomena are characteristic, closely resembling pyemia. The best example of the nonsuppurative variety is femoral thrombophlebitis (*phlegmasia alba dolens*). The diagnosis of pelvic thrombophlebitis is extremely difficult. After several days of apparent normalcy the patient becomes febrile and complains of pelvic pain. Examination fails to reveal any evidence of local disease. Fortunately in the majority of cases the infection is limited and of the nonsuppurative type. Spontaneous recovery is the rule. For the most part, suppurative thrombophlebitis occurs in conjunction with endometritis, pelvic cellulitis, etc. Specific therapy has already been instituted to combat the primary infection and is the best means of prevention against resultant embolism.

Femoral thrombophlebitis was formerly treated by complete rest of the affected leg, elevation to an angle of 30 degrees and a firm supportive bandage to limit swelling. Hot moist packs were also used in the hope of preventing chronic venous congestion. Under this regimen the infection usually subsided in anywhere from ten to sixteen days. Several years ago this method of treatment was supplanted by paravertebral nerve block. The rationale for this plan is based upon the concept that vasospasm which results from afferent impulses arising in the injured vein segment was primarily responsible for the development of thrombophlebitis. When this procedure was carried out the relief of pain was prompt and the disappearance of edema rapid. Thus the duration of the infection was materially shortened. Heparin has also been used with considerable success. The use of this drug, however, is not without danger. At the present time we advocate *continuous caudal or continuous spinal anesthesia*. In our opinion its superiority over paravertebral nerve block is due to the marked vasodilatation

which occurs and is maintained for the duration of the anesthesia. Most recently we have employed continuous spinal, using 1.5 per cent metycaine. One cubic centimeter or 15 mg is given at intervals of forty minutes. The duration varies with the severity of the infection. In our series, which up to the present time is small, the shortest period of time has been four hours and the longest twelve hours. Relief of pain is immediate, and usually within five to ten minutes vasodilatation of the extremities is manifested by marked warmth and redness. In most instances edema disappears within twenty-four hours, the temperature returns to normal and the patient is allowed out of bed at the end of seventy-two hours. Further trial will of course be necessary in order to properly evaluate this plan of treatment.

Infected Abortion—The treatment of this serious and often fatal infection has been reserved for discussion separately, because up to the present time there is considerable controversy as to the best method of management. On the one hand we have a group of conservatives who insist that a "hands off" policy is the only safe course, while on the other hand a second group equally as sincere maintains that active interference gives the best results.

Under the conservative plan the treatment is directed toward the infection with complete disregard for the retained products of conception. In addition to routine supportive measures for any puerperal infection, penicillin or a sulfonamide is given. The dosage and method of administration is dependent upon the severity of the infection and do not differ in any way from the plans previously described in the treatment of endometritis, pelvis cellulitis, and so forth. Only after all acute features of the infection have subsided and the temperature has remained normal for several days is it deemed safe to empty the uterus. This is accomplished by simple evacuation and blunt curettage. This rule of "stay out of the uterus" while active infection is present may be disregarded only in cases of severe hemorrhage which may necessitate the removal of secundaries protruding through the cervical canal or the insertion of a vaginal pack.

The radical plan of management is based upon the concept that the unexpelled products of conception rapidly become necrotic and as such are a fertile field for the growth and multiplication of pathogenic bacteria. Such a concept is at least partially substantiated by the fact that spontaneous expulsion of the retained products of conception is in the vast majority of cases promptly followed by recovery. In our clinic the radical plan was adopted three years ago and up to the present time results have been most gratifying.

The method is as follows: Upon admission, a cervical culture is immediately taken (using the technic described under Endometritis) and a twenty-four hour report is requested. Sulfadiazine therapy is immediately instituted, giving an initial dose of 2 gm followed by 1 gm every four hours. The general condition of the patient is deter-

mined by thorough physical examination, complete blood count, blood sedimentation and urine analysis in order to evaluate the operative risk. If the patient's general condition is satisfactory, preparation for operation is made. The final decision is dependent upon the laboratory report. If the *Streptococcus hemolyticus* is recovered, surgical interference is definitely contraindicated and the conservative plan is followed, otherwise the patient is removed to the operating room regardless of fever and the uterine contents are completely evacuated. The uterus is then firmly packed with either sulfanilamide or iodoform gauze which is to be removed in twenty-four hours. Depending upon the organism recovered from the cervical culture, sulfadiazine may be continued or penicillin therapy instituted. Usually at the end of forty-eight hours the patient's temperature has returned to normal and she is able to get out of bed.

In our opinion the so-called radical plan possesses definite advantages over conservative management, to wit (1) recovery is much more rapid, (2) the length of hospitalization is materially reduced, and (3) the end result is equally as good.

VACCINATION DURING PREGNANCY AS A PROPHYLAXIS AGAINST PUERPERAL INFECTIONS

J BERNARD BERNSTINE, M D , F.A.C.S *

THE problem of immunity to puerperal sepsis has attracted the attention of clinicians and biologists ever since the bacterial origin of infection has been recognized. In 1923 and 1925 Dick and Dick inaugurated a cutaneous test for the toxin of scarlet fever. Later, this test was extended to the field of obstetrics and patients were examined for susceptibility by the Dick method. These investigations added much to the knowledge of immunity to certain strains of the streptococcus and have emphasized the importance of the natural resistant agents of the body in combating and eradicating infection.

The problem in puerperal sepsis, however, goes beyond the question of streptococcic infection alone. While the most severe of the blood infections are generally due to hemolytic strains, many other morbid lesions are produced by bacilli of the colon group and various other cocci. With these facts in mind we have undertaken to culture the types of organisms commonly found in puerperal infection, test their effect upon laboratory animals, and by means of a vaccine made from the cultures, endeavor to elevate the immunity of the pregnant woman to puerperal infection in general.

The content of this paper has to do with the technic of preparation, the experimental trials in mice, and the results obtained by the use of the vaccine. The number of cases reported to date including the latest group totals 973 cases.

Our first problem was to study carefully the bacteriology of the birth canal, especially the cervix and endocervix of pregnant women. The bacterial strains employed in the vaccine used in this study were obtained from the patients (pregnant women) attending the antenatal clinic of the Philadelphia General Hospital. The cases studied were picked at random and not selected, the only requirements being that the patient employed should have had no sexual intercourse for at least twenty-four hours preceding the taking of the cultures, and she must not have taken a vaginal douche.

The patient thus employed was placed in the dorsal position, and a dry, sterile bivalve vaginal speculum was introduced into the vagina. The other hand, still being uncontaminated, was employed in obtain-

From the Department of Obstetrics, Jefferson Medical College Hospital, Philadelphia.

Associate Professor of Obstetrics, Jefferson Medical College. Attending Obstetrician, Jefferson Medical College Hospital.

ing the cultures The first was taken from the cervix with a sterile cotton swab, and the assistant immediately placed this specimen in a sterile tube containing blood agar, solidified, to prevent its drying The second specimen was taken from the endocervix, and treated likewise All specimens were taken to the laboratory and subcultured within thirty minutes from the time they were obtained

CULTURAL MEDIA AND METHODS

For the purpose of isolation and identification of organisms, we employed 5 per cent defibrinated horse blood agar plates and slants, beef infusion broth, pH 7.6, and plain 2.5 per cent infusion agar plates and slants In the case of gram-negative bacilli, their identification was made certain by their carbohydrate fermentation reactions

Each of the two specimens was streaked to each of two blood agar plates and then the swabs were placed separately in test tubes containing 5 cc of beef infusion broth One of the blood agar plates from each specimen was incubated under partial oxygen tension, the two remaining plate cultures being kept at normal aerobiosis The reduced oxygen tension was obtained by placing the cultures in Novy jars and partially evacuating the air by means of a Cenco-Hyvac pump All cultures were then incubated for twenty-four hours at 37.5° C., when they were examined for growth, grossly and microscopically The broth cultures were subcultured to blood tension for twenty-four hours or longer No culture was considered negative for growth until after an incubation period of at least seventy-two hours No direct smears from patients were made, since we were interested only in bacterial growth However, routine smear preparations are studied on all patients in this clinic for evidence of neisserian infection

In the series of twenty-five cases studied we failed to recover any organisms from the cultures grown under partial oxygen tension which we did not obtain in cultures grown at normal oxygen tension The gonococcus was conspicuous by its absence in all cultures

The strains to be incorporated later in a vaccine were placed in pure culture on suitable media and stored at a temperature of 6° C as soon as their isolation and identification were made

The complete bacterial flora of the series studied is shown in Table 1 We have not listed the cultural results from the cervix and endocervix separately, because we found only a slight and insignificant variation in the bacterial flora from the two sources

PREPARATION OF THE VACCINE

The majority of the various strains of organisms incorporated in the vaccine were pathogenic for mice Only strains which grew smoothly in broth and produced smooth colonies as solid media were employed All of these latter strains were grown by repeated transfer in broth for four successive days and then the growth from an eighteen-hour culture was collected in sterile physiologic saline, washed once with normal saline and standardized to 2 billion per cc by the turbidity method, using as standards of comparison suspensions of staphylococci in gelatin of a 2 billion per cc concentration All streptococci were collected by centrifuging the eighteen-hour growth obtained from cultures in beef infusion broth, pH 7.6 The remaining strains of organisms employed in the vaccine were grown on beef infusion agar slants The eighteen-hour growth was washed from these slants with sterile normal saline, washed once and standardized as above noted

* Colonies hemolyzed blood agar

Each of the separately collected vaccines was subcultured to blood agar to rule out contamination. The vaccines were then killed by the addition of sufficient 5 per cent alcoholic solution of thymol to make a concentration of 0.4 per cent thymol, and were stored at 6° C overnight. On the following day each of the vaccines was diluted with an equal volume of sterile normal saline thus giving a concentration of 1 billion per cc. These diluted vaccines were placed in sterile 60 cc vaccine bottles and tested for sterility by subculturing to blood agar slants, the latter being incubated aerobically and anaerobically for forty-eight hours. The bottles were then stoppered with appropriate rubber stoppers, the latter being sealed by the application of collodion. These vaccines were then properly labeled and stored continuously at 6° C as stock suspensions of killed single type organisms from which a mixed vaccine could readily be made. The accompanying outline summarizes the types of vaccines employed in the final mixed vaccine used in our studies (Table 2).

TABLE 2—COMPOSITION OF THE MIXED VACCINE

	No. of Strains	Proportion, Per Cent
1. <i>Streptococcus hemolyticus</i>	5*	35
2. <i>Streptococcus viridans</i>	8	15
3. <i>Staphylococcus aureus</i>	2	25
4. <i>Bacillus coli communis</i>	2	15
5. <i>Streptococcus nonhemolyticus</i>	4	10

* Four of these strains were recently isolated strains, 2 were isolated from the blood, and 2 from the lochia of patients with puerperal infections.

When it was found that all of these individual vaccines were sterile, a mixed vaccine was prepared, varying the percentage content of the various strains of organisms according to the above designated proportions. The desired quantity of each individual vaccine was removed from the "stock" bottle aseptically with a Luer syringe and hypodermic needle and the six fractions were pooled in a small sterile flask. An equal volume of sterile saline was then added to the flask and after thoroughly mixing its contents, this final preparation was transferred to 30 cc vaccine bottles. These were proved sterile by subculturing and further cared for by methods above noted.

It will be noted that the last saline dilution reduced the concentration of organisms to $\frac{1}{2}$ billion per cc., while at the same time the concentration of thymol was reduced from its original killing concentration of 0.4 per cent to a preservative concentration of 0.1 per cent. This concentration of organism and of chemical has proved satisfactory in a large series of cases observed by us. We can readily employ the necessary dosage with no demonstrable reaction attributable to the chemical preservative.

RESULTS OF TESTS ON ANIMALS AND NONPREGNANT WOMEN

It is considered inadvisable by some authorities to vaccinate women during pregnancy, but there was conspicuous lack of tangible evidence in the literature to substantiate this belief. However, before attempting vaccination of pregnant women, we employed the vaccine repeatedly in mice. We then vaccinated a series of nonpregnant women of child-bearing age.

Twelve mice were divided into Groups A and B of 8 and 4 mice, respectively. Two experiments were conducted simultaneously on these groups. Group A was immunized by repeated injections of the vaccine, beginning with 0.1 cc. and increasing the dose until nine injections had been given at regular intervals over a three-week period. The final dose was 1.0 cc. and all mouse injections were given intraperitoneally. Ten days after the last injection, all mice of Group A were inoculated with a lethal number of living organisms obtained from young cultures of our isolated strains, one strain each of *Streptococcus viridans* and of *Streptococcus hemolyticus* being employed. This lethal dose was determined by inoculation of a series of nonvaccinated (normal) mice, when it was found that 0.5 cc. of an eighteen-hour broth culture of streptococci was uniformly fatal in twelve hours or less. All of Group A survived, and two litters of apparently normal mice were found among these animals during the study.

Mice of Group B were subjected to single, large doses of vaccine intraperitoneally. Doses of 0.3, 0.5, 0.75, and 1.0 cc., respectively, were given. As in Group A, these mice were observed for reactions. The two mice receiving the larger injections appeared to have a moderate reaction and were sluggish for several hours following the injection, in contrast to Group A mice which showed no reactions. However, on the days following vaccination Group B mice showed no evidence of untoward reaction and were normal in appearance. There was born a normal litter to Group B also.

Following our studies on mice, ten female patients who were already hospitalized were selected for study. These women were not pregnant, but were of the childbearing period, free from acute infectious diseases and well informed of the nature of the studies we wished to make. (Some of these patients were ambulatory while others were bedridden.) Careful records were kept in which the pulse, temperature, respiratory rate, blood pressure and urinalysis were recorded. They were observed especially for evidence of local or general reactions to the injections.

All of these women were first given an intracutaneous injection on the flexor surface of the forearm of 0.05 cc. of the vaccine. Subsequent injections were given subcutaneously over the deltoid region at four-day intervals until a total of ten injections had been given each woman. The dosage was gradually increased from 0.05 cc. to 1.0 cc. at the tenth and final injection. Aside from an occasional complaint such as slight soreness at the site of injection or mild malaise, no untoward reactions were observed. Among this group of women were several postencephalitics and cases of multiple sclerosis. Though this study was obviously not therapeutic in its aim, several of this group volunteered information to the effect that they had improved and felt better following vaccination.

VACCINATION OF PREGNANT WOMEN

The observations and results obtained by the vaccination of mice, and also of nonpregnant women of the childbearing period, were not only gratifying but encouraged us to proceed with the actual vaccination of the pregnant woman

The reports of studies were presented in four groups Group I presented in 1936 consisted of 51 vaccinated pregnant women Group II consisting of 177 similarly vaccinated cases was reported in 1939 Group III was presented in 1941 and consisted of 271 additional patients Group IV or the latest number of vaccinated cases includes 471 additional patients As was mentioned above, Groups I, II, III have been reported previously, therefore, this treatise will deal mainly with Group IV. This study (Group IV—471 patients) was conducted entirely on patients attending antenatal clinics of Jefferson Medical College Hospital. Patients were accepted for vaccination irrespective of their past or present medical or obstetric histories, their acceptance depending only upon their willingness to cooperate in this study Routine studies on these women consisted of the following complete history (medical and obstetric), physical examination, urinalysis, blood pressure and weight determination (at each weekly visit) Complete blood count and blood Wassermann and Kahn tests were performed Other studies and observations were made when the occasion demanded

This report includes the observations on 471 women in our present series during the antenatal period, labor and puerperium Additional observations were also made on the babies born to these women

PROCEDURE OF VACCINATION

All injections were administered with a tuberculin syringe and a 25 gauge hypodermic needle The skin at the site of inoculation was first prepared by cleansing with sterile water, then sponged with 95 per cent alcohol Each patient was first given an intracutaneous injection of $\frac{1}{2}$ minim of vaccine on the flexor surface of the forearm, and then observed for local and general reactions at from one to three day intervals Subsequent injections were given at weekly intervals, intramuscularly in the deltoid region The initial intramuscular injection was 1 minim, the second injection 2 minims, with subsequent injections as follows 4, 8, 12 and 16 minims The maximum dose was the one administered until the patient was delivered The total number of injections varied in individual cases of this present series (Group IV) from a minimum of 8 to a maximum of 30 Figure 186 illustrates the period of gestation during which the vaccine was administered It will be noted that the majority of the patients received their vaccinations from the fourth to the ninth month This corresponds with the approximate time of gestation when they registered in the outpatient obstetric department.

The types of complications observed in our vaccinated group may be generally accepted as factors predisposing, either directly or indirectly, to puerperal infections. It is common knowledge that local or general complications during pregnancy often bear an important relationship to the incidence of puerperal morbidity. The group of complicated cases in this study demonstrates feasibility of vaccination with regard to tolerance in the pregnant women with abnormalities.

The delivery of these patients should be considered very carefully. We deemed it unwise for the physicians in attendance to have knowledge of the prophylactic vaccination, since it was our aim to have different men deliver these patients. This was done only to aid in obtaining results that would be impartial and unbiased.

TABLE 7

Features of Labor	No of Cases	Features of Labor	No of Cases

Surgical induction	10	Scanzoni's maneuver	1
Medical induction	6	Adherent placenta	2
Born before doctor arrived	2	Cardiac decompensation	1
Forceps (low)	75	Annular detachment of cer- vix	1

It is not within the scope of this paper to give in detail a description of the labor and delivery of this entire series. Table 7 illustrates the incidence of certain features of delivery which should be taken into consideration, since it is a known fact that the conduct of labor has a direct bearing on puerperal morbidity. There were 343 patients in this series who delivered themselves spontaneously and the remainder had operative interference.

PUERPERAL MORBIDITY

Our criteria for puerperal morbidity are based upon the accepted standard at the Jefferson Medical College Hospital, to wit, any elevation reaching 100.4° Fahrenheit on any two readings or two successive readings exclusive of the first twenty-four hours following delivery that the patient is considered morbid.

In our series of vaccinated cases, twenty patients were morbid during the puerperium, a total of 4.24 per cent, as compared with the

nonvaccinated group for the same period who showed a puerperal morbidity of 17.1 per cent

TABLE 8.—CAUSES OF PUERPERAL MORBIDITY IN VACCINATED GROUP

Cause	No of Cases
Cesarean section (operation reaction)	16*
Degeneration of uterine myoma postpartum	1
Cramotomy and embryotomy	1
Cystitis	1
Rupture of Bartholin's abscess during labor	1

* One cesarean section not morbid.

HOSPITALIZATION PERIOD

The patients in the vaccinated series showed a variation from a minimum of five to a maximum of thirty-three days' hospitalization (Table 9). The factors which necessitated longer hospitalization were

15 days (4 cases)

- a. Negro, age 27, gravida I, rheumatic heart disease, contracted pelvis, cesarean section
- b. White, age 17, gravida I, eclampsia, contracted pelvis, cesarean section when recovered from eclampsia
- c. Negro, age 16, gravida I, cephalopelvic disproportion, cesarean section
- d. Negro, age 25, gravida I, admitted to hospital in labor and febrile, android pelvis, deep transverse arrest of head (original R.O.P.), intrauterine fetal death, forceps delivery, delivered of macerated fetus

16 days Negro, aged 25, gravida V, cardiac disease, decompensated during pregnancy, cesarean section and sterilization

21 days (2 cases)

- a. Negro, aged 18, gravida I, severe preeclampsia, surgical induction of labor, spontaneous delivery (L.O.A.), mediolateral episiotomy, primary repair
- b. Negro, age 21, gravida I, premature separation of placenta (complete detachment of placenta), cesarean section, blood transfusions before and after operation, reaction following transfusion

33 days White, age 24, gravida I, rheumatic heart disease, mitral stenosis, mid-forceps (R.O.P.), acute cardiac decompensation, remained in hospital for cardiac condition as medical case.

TABLE 9 —HOSPITALIZATION PERIOD

Days in Hospital	No of Patients	Days in Hospital	No of Patients
5	1	12	9
6	4	13	2
7	22	14	7
8	160	15	4
9	214	16	1
10	41	21	2
11	3	33	1

Note 93.8 per cent of patients in the series remained in the hospital ten days or less, 98.3 per cent were in the hospital two weeks or less

BABIES BORN OF VACCINATED MOTHERS

A study of these vaccinated persons would not be complete unless it included observations of the newborn. There were 251 males and 225 females, with their weights ranging from 2 pounds to 10 pounds 4 ounces (Table 10), and there were six sets of twins. In the entire

group there was one abortion, which was induced, and seven stillbirths. An explanation of the stillbirths follows

1. Premature, polyhydramnios.
2. Premature, premature rupture of membranes, breech, prolapsed cord.
3. Mother a severe preeclamptic (blood pressure systolic, 270 diastolic, 210), necrotic placenta, spontaneous delivery
4. Premature.
5. Premature, one of twins (uniovular)
6. Moderately contracted pelvis, labor 74 hours, midpelvic arrest of head, for cephs delivery, macerated.
7. Craniotomy and embryotomy (macerated)

It is felt that anything which might influence puerperal morbidity or mortality or possibly decrease the incidence of puerperal infection is worthy of consideration.

F. L. Adair has stated that 90 per cent of 7380 obstetric deaths were due to sepsis. L. Colebrook is authority for the statement that the present condition is roughly this. Casualties from infection represent nearly 50 per cent of the total deaths directly associated with child-bearing if those due to abortion are included, and, in addition, there is a large amount of serious nonfatal illness. Therefore, we believe that if anything can be employed in an attempt to increase the resistance of pregnant women to puerperal infections, it should be given consideration. It would be ridiculous to say that puerperal infections can be abolished entirely and forever; but, on the other hand, it is not impossible for such infections to be reduced to a minimum.

I would like to cite one case as an example of what may happen to a patient in labor and the possibilities that may arise and contribute towards puerperal infection.

Patient C T, 26 years old, white, gravida III, received eleven injections of vaccine during pregnancy. She went into labor at term, and delivered spontaneously a male child weighing 9 pounds. The child was born before the arrival of the doctor, and was expelled on the bathroom floor. A kind neighbor severed the umbilical cord and tied it. The doctor arrived and the placenta could not be expelled. The patient was removed to the hospital where the placenta was manually removed. She made an uneventful recovery and left the hospital in eight days and at no time was she morbid.

ANALYSIS OF RESULTS

The first three series of cases that were presented totaled 502 vaccinated patients. In this present series we have observed an additional 471 cases, making a total of 973 vaccinated patients. As stated before, the patients were not hand picked, in reality, we hoped to obtain a representative group such as may be found in a cross section of the average obstetric practice with its associated complications, namely, primiparous and multiparous women during pregnancy, labor and the puerperium.

The vaccine was administered to pregnant women with various complications in addition to their pregnant state. These complications varied in type and severity, and yet we failed to observe a single case that presented an aggravation of the preexisting condition.

For the entire series, unvaccinated cases under similar conditions and delivered by the same personnel served as a control.

The morbidity for the present vaccinated group was 4.24 per cent (that is, for 471 cases) and 4.6 per cent for the combined group including the 502 vaccinated cases previously reported (total—973 cases).

The morbidity for the nonvaccinated group in this series of 471 cases was 17.1 per cent and for the combined group including the cases previously reported it was 19.66 per cent.

SUMMARY

A method has been presented whereby a vaccine was prepared and used in an attempt to immunize a series of pregnant women: series 1, 51 cases, series 2, 177 cases, series 3, 274 cases, and series 4 (present report), 471 cases, total 973 cases. The following points may be considered salient features of these studies:

- 1 Active immunity was conferred to mice by means of repeated injections of vaccine.

- 2 The safety and absence of reactions to the vaccine were demonstrated.

- 3 Preexisting conditions in these cases, whether acute or chronic, were not aggravated by vaccination.

- 4 In the entire four series which includes the present report, 973 patients were delivered with no fatalities. In a communication with the Philadelphia County Medical Maternal Mortality Committee, it was noted that in the years 1935 to 1944, inclusive, there had occurred

441 maternal deaths due to puerperal sepsis. The puerperal morbidity was 4.6 per cent as compared with a morbidity of 17.1 per cent in nonvaccinated cases.

In conclusion, I wish to state that a larger series of patients are being vaccinated, and that special studies were conducted on vaccinated pregnant women, and on a large group of vaccinated medical students (all males) and it was determined by serological tests that in both groups there was a definite and significant rise in antibody titer. These last two studies, which were conducted in cooperation with Dr George P. Blundell, will be reported in detail in the future.

SOME PSYCHIATRIC PROBLEMS IN OBSTETRICS AND GYNECOLOGY

Diagnosis and Treatment

JOSEPH C YASKIN, M D *

THE aim of this presentation is to discuss the psychiatric aspects of some of the problems in obstetrics and gynecology in a manner that will enable the clinician to attain a classified idea for purposes of diagnosis and treatment. To accomplish this, the clinician need acquire a few principles in psychopathology and psychotherapy which are as essential in psychiatry as are anatomy, physiology, chemistry, pathology, pharmacology and surgical technic in organic medicine and surgery

SOME BASIC PRINCIPLES IN PSYCHOPATHOLOGY

To understand the psychiatric aspects of his individual specialty, the clinician must possess a few principles regarding the structure and function of personality, types of personality, the various reaction types and in the case of the neuroses, some psychological mechanisms. These will be briefly defined and discussed.

Personality.—Personality is the sum total of all the reactions in a given individual. It includes the habitual patterns of behavior of the individual in terms of physical and mental activities and attitudes (Healy, Browner and Bower¹). Personality is *dynamac* from birth to death. Its development begins with the *instincts* inborn, unlearned drives which though repressed, suppressed and modified in many ways, remain the great driving force of the personality. The cementing and supporting energy of the *instinctual* drives is emotion. In the course of development there is a constant struggle between the inborn tendencies on one hand, and the demands of the outside world on the other. This everlasting struggle determines impulse, temperament and character and the modes of thinking, feeling and acting. For the scientifically and organically minded clinicians, one may offer a crude but accurate analogy which may be found in the development and reactions of the various organs in the body.

A fundamental, empirical, but necessary concept of personality necessitates the division of the personality into two parts, *unconscious* and *conscious*. The unconscious monopolizes the greater part of per-

From the Department of Neurology and Psychiatry, Graduate Hospital, University of Pennsylvania, Philadelphia.

* Professor of Neurology, Graduate School of Medicine, University of Pennsylvania.

sonality It has often been compared with the submerged part of an iceberg, the visible part representing the conscious. The unconscious is defined as a deep level of mental activity consisting of elements which never were conscious (collective unconscious of Jung²), and of elements previously in consciousness but forgotten, suppressed or repressed. *Suppression* is a purposive exclusion of ideas from the field of conscious attention. *Repression* is an unconscious exclusion of painful and unpleasant material from consciousness and from motor expression. Repression is directly or indirectly accomplished by that part of the personality which is concerned with the adaptation of the individual to the needs of reality The unconscious is brought into consciousness only in dreams, abnormal states and by special psychological technic. The conscious part of the personality is at all times markedly influenced by its larger unconscious part.

It should be stressed that the unconscious is not a static, inert mass. It is a form of energy and, as such, has *dynamic* possibilities This energy, accumulated as it is in the course of adaptation and development from infancy onward, is incorporated into certain units called *complexes* A complex is an unconscious constellation of ideas held together by an affective (emotional) charge and therefore in some way related to instinctive processes. Most of the unconscious consists of material which is evolved in successful integration. Some of the complexes are residues of poorly solved conflicts which are excluded from consciousness due to their lack of harmony with the conscious part of the personality and its tendencies. These complexes, which are poorly integrated in the personality, usually develop early in life, and frequently have their origin in reactions peculiar to earlier life. These reactions consist of phantasies, incidents and situations which have their origin in childhood and which are forgotten but are projected into adult life in a symbolic form (Yaskin³)

Poorly integrated parts of the unconscious express themselves in dreams, in sublimations, in character traits and in the presence of *precipitating* causes, in *symptom* formation. These symptoms may be in the physiological or psychological spheres, or both The manifestations are usually in the form of disguises or symbols which have no clear semblance to the original situation any more than universal edema has to the failing kidney

When one considers the personality from this viewpoint, it is easier to understand how a given physiological disturbance is a symbol of a psychological disturbance which can only be understood when the personality is properly evaluated Without such an approach, both diagnosis and treatment are unsatisfactory

Types of Personality—It is highly desirable but difficult to classify personalities into types. For the present the author in practice uses the following classification, which is undoubtedly open to many objections but which has been found useful, nevertheless

1 **AVERAGE NORMAL.** This may be defined as the type who makes a satisfactory economic, social, marital and sexual adjustment, who performs efficiently without symptoms or marked emotional swings, who most of the time gets satisfaction from his life experiences, and whose reactions to various stresses and strains are adequate and efficient.

2 **NEUROTIC PERSONALITY** The neurotic personality is characterized by manifestations intermediate between normal character traits and neurotic symptoms (Jones⁴) In the neurotic personality the "neurosis is built into the character" The neurotic symptoms vary considerably with the type of neurosis and will be discussed later Here it may be well to emphasize some features more or less universal in all neurotic personalities The basic psychopathologic process is one of *anxiety* or its many modifications or substitutes *Hostility*, overt or concealed, is often present The neurotic traits always develop *early in life*, are modified by the many life experiences, usually manifest themselves by subtle attitudes and reactions, and become *symptoms* under the impact of appropriate precipitating causes

3 **SYNTONIC TYPE (Cycloid, Extraverted)** This is characterized by swings of mood beyond those observed in the average normal The moods in these individuals determine the behavior in their everyday activities The syntonetic type is a predisposing cause to manic-depressive reactions

4 **SCHIZOID TYPE (Shut-in, Introverted)** A good description of this type is at present not available These individuals are characterized on the one hand by marked sensitiveness and on the other by unapproachable coldness Regardless of the proportion of these qualities, the schizoid *lives within himself* (Noyes⁵) This type of personality is apt to develop dementia praecox

5 **PARANOID TYPE.** This is characterized by the tendency to misinterpretation, abnormal suspicion, and stubbornness, and by consequent mood and behavior disturbances leading to poor adjustment This type is apt to develop dementia praecox and paranoid reactions of other types

6 **RIGID TYPES** This type of an individual is overly serious, overconscientious, overmeticulous, strictly conventional, abnormally honest, preoccupied with problems of security and generally engrossed in immediate problems so that the future horizon is rather circumscribed This type is more common in women and is apt to develop involution melancholia

7 **CONSTITUTIONAL PSYCHOPATHIC TYPE.** This type of individual is neither insane nor intellectually deficient These individuals lack emotional and volitional stability, and "stick-to-itiveness," and do not benefit by experiences, so that they make poor economic, social and marital adjustments They include the pathological liars and swindlers, the nomadic personalities, the antisocial individuals, some paranoid types and some sexual psychopaths

Reaction Types—The various mental reactions are intimately related to the various personality types From the standpoint of psychopathology it is well to be familiar with the several reaction types These include

1 The *organic* reaction type, such as occurs in structural diseases of the brain due to vascular and degenerative changes, neoplasms, infections, intoxications and deficiency states, and characterized by psychotic, predominantly intellectual, difficulties

2 The *affective* reaction type, comprising principally the cyclic manic-depressive reactions and involutional melancholia

3 The *schizophrenic* reaction type, with many bizarre modes of thinking, feeling and acting observed in various types of dementia praecox

4 The *psychoneurotic* reaction type, which is the most frequent type and

should be understood by all clinicians. The psychoneuroses and neuroses may be defined as conditions characterized by a variety of subjective complaints without any primary structural or chemical causes to account for their existence and generally traceable to some disturbance in the psychological processes of the individual. In the psychoneuroses the causative factors are traceable to occurrences and phantasies of early life with reactions to these incidents in the form of personality traits. In the neuroses the causative factors are traceable to occurrences or situations in the recent past or immediate present. In this presentation the term "neuroses and psychoneuroses" will be referred to as "neuroses."

The psychopathology of the neuroses is complex and for detail the reader is referred to other publications (Yaskin⁶). Here it may be well to submit the following formulations. For practical purposes the concept neurosis implies the absence of any primary structural or chemical disease, the existence in the majority of cases of a certain constitutional make up (the predisposing cause), the occurrence of precipitating or exciting causes, and the formation of symptoms which may be in the psychic or in the physiologic sphere, or both.

From the standpoint of the neuroses, the most important aspect of the personality is the emotional (affective) reaction. These emotional reactions may have their origin in situations of which the patient is perfectly aware (in the conscious) or in occurrences of phantasies of the past of which he is totally unaware (in the unconscious). The existence of the unconscious has not been proved but, at present, it is a necessary hypothesis in the management of the neuroses. The unconscious activities of the personality are comparable to the activities of most of the thoracic and abdominal viscera of which we are not normally aware but which nevertheless exert a determining influence on our very lives. It is only when the viscera become disturbed that we become aware of them by reasons of symbols which we call symptoms. Symptoms in organic medicine are often clever disguises, as edema in Bright's disease, glycosuria in pancreatic disease, and so on. It has taken thousands of years to correlate the bizarre symbols with their true causes. This tendency for nature to disguise and symbolize is even more marked in psychopathology and makes the subject at times very complex, but, just as in organic medicine, there is always a chain of events to account for the occurrence of the various phenomena. Most of us can as easily understand the occurrence of tachycardia, vomiting, diarrhea or fainting as an immediate result of some great emotional shock as easily as we understand vomiting in obstruction of the gastrointestinal tract or the tachycardia in the failing heart. Some may doubt that insomnia, abnormal fatigability and irritability, phobias and many visceral disturbances are entirely due to emotional disturbances which occurred years before the development of the symptoms, although none of us at present question that tabes and other marked changes in the various organs had their origin in a humble small cutaneous lesion called a chancre. It is a fact, nevertheless, that many neurotic symptoms are prolongations of early emotional

states which remain dormant in the unconscious part of our personalities until some exciting cause activates them

Symptom formation results from the action of some exciting cause which may be an injury, infection, a chemical disturbance or some emotional stress. The symptoms may continue long after the exciting cause ceases to operate, and thus represent released phenomena of the neurotic traits of the previously apparently well integrated personality. These symptoms include either frank anxiety states or symptoms tending to avoid anxiety such as conversion, compulsive-obsessive neurotic reactions. These symptoms vary in severity from a slight headache, increased fatigability and irritability, to devastating visceral disturbances, intractable insomnia with marked agitation, and alarming loss of weight. The clinical manifestations frequently completely overshadow the primary constitutional factors or the immediate precipitating mechanisms.

Anxiety is the central symptom of nearly all the neuroses and psychoneuroses and is of fundamental importance in the management of all neuroses. Anxiety may be defined as one of the clinically important major emotions recognized introspectively as an unpleasant feeling, accompanied by fear without any, or without adequate cause, and manifested objectively by abnormal changes in the neuromuscular, autonomic, and secretory functions (emotional expressions). All neurotic symptoms are derived from anxiety arising in the conscious or unconscious parts of the personality. These symptoms include frank anxiety or conversions and substitutions for anxiety reflected in disturbances in the physiological or emotional spheres.

There are many mechanisms by means of which anxiety is converted into symptoms and those interested will search for these in publications on psychopathology.¹ Here it is worth stressing the role that *hostility* plays in a good many neurotic conditions. Anxiety gives rise to hostility, which in turn generates more anxiety and thus a vicious circle is established. Both the anxiety and hostility are experiences of which the patient is not at all or only poorly aware. The existence of both anxiety and hostility help to explain the reasons why "the neurotic person may at the same time be driven imperatively toward dominating everyone, toward complying with others and imposing his will on them, toward detachment from people and craving for their affection. It is these utterly unsolvable conflicts which are most often the dynamic center of the neuroses. The two attempts which most frequently clash are the striving for affection and the striving for power" (Horney⁷).

It is well to remember that a given group of symptoms is only a conspicuous part of the total neurosis and that the several types of neuroses differ considerably in their etiology, psychopathology, prognosis and treatment.^{1 6}

PSYCHOTHERAPY

Psychotherapy is a procedure which aims to correct the underlying psychopathic difficulties as well as the various symptoms of which the patient complains. It is a psychological device used to change the attitude of the patient toward himself, toward his physical and mental processes, and toward his environment. It is an attempt to reevaluate his various life problems in relation to his various symptoms in the light of intellectual and, especially, emotional experiences.

For purposes of systematic description, psychotherapy is divided into the following artificial steps:

Rapport—This is a relationship between physician and patient whereby the latter gains confidence in and respect for the therapist, and at least a desire to cooperate despite preconceived notions of the origin of his symptoms. Rapport is indispensable for successful treatment and is probably the most important step in the treatment. To attain the attitude of a satisfactory rapport the patient must feel that the physician not only sympathizes with him but also that he has a clear formulation of his case and has the ability to help him. To justify to the patient's expectations the physician must not be too hasty in arriving at conclusions but once the formulation is made he must remain firm in his statements, betray no doubts or indecisions, and above all be frank and truthful.

Ventilation or Aeration—This consists of bringing into conscious attention in specific detail unwholesome attitudes and reactions which are usually associated with irritating memories. Some material is usually elicited in a detailed initial history. More information will be given by the patient when he is permitted to talk freely in direct interviews. Often, however, it is necessary to use the free association method.

Desensitization—This consists in removing the unpleasant emotional tone attached to the memories by intellectual discussion. The patient is encouraged to face openly the unpleasant experiences and memories of the past. To accomplish this the material must be brought into consciousness repeatedly. This is done either by direct interviews or by the free association method. In the course of time there is usually a better objective understanding by the patient, and, what is more important, the emotion loses its unpleasant "sting."

The physician should guide the patient in this phase of the treatment. An element of suggestion is neither unavoidable nor undesirable, provided the therapist does not abuse it. It is necessary that the desensitization should be gradual to avoid severe "shock" reaction, avoiding undue wounding of sensitivity and pride, and slowly building up tolerance to unpleasant emotional realizations.

It is best to leave most patients with some formulation at the end of each treatment period.

Retraining, Reeducation and Stabilization—This consists in guiding the patient to react more or less automatically in a symptomless, efficient and wholesome manner to various stresses in life. To be more or less automatic the responses have to be free from unpleasant emotional tone. This is accomplished by desensitization, and must be learned, at least in the adult, by persistent conscious effort. As a necessary part of lasting successful retraining and reeducation the patient should be guided to formulate an economic, social and recreational plan which will vary markedly with the individual patient.

Other Procedures—Psychotherapy of the family is often an important part in the management of many cases. Included in the several procedures are elements of encouragement, suggestion, rationalization and persuasion irrespective of the type of psychotherapy used. Often the mental illness is complicated by various stresses such as marital, social or economic, which cannot be eliminated and under such circumstances the patient is guided to face the hard facts in the situation and work out some compromise.

In addition to the purely psychological methods the clinician often employs methods which are partly psychological and partly physiological such as a regimen at home or at work, hospitalization, and occupational and physical therapy. Also purely physiological approaches are useful and at times necessary. These include sedatives, somnifacients, narcosis, tonic and endocrine agents, and attention to nutritional and hygienic needs.

The psychotherapy of the different types of neuroses cannot be discussed here and the reader is referred to other publications on this subject^{3, 6}

PSYCHIATRIC ASPECTS IN SOME SPECIFIC PROBLEMS IN OBSTETRICS

The obstetrician and gynecologist is not expected to have a profound knowledge of psychiatry but should possess a few principles which may be useful in his practice. A knowledge and record of personality make-up, the manner in which the patient thinks, feels and acts, a few notes on the *mood* of the patient at a given examination, the presence of fears, obsessions, compulsions, unusual preoccupations or a tendency to misinterpret, may be helpful in the subsequent management of the case.

There are, in addition, a number of specific problems in pregnancy and in the postpartum period and in gynecologic practice which have definite psychiatric implications, and these will now be discussed in relation to psychopathology and psychotherapy.

Psychiatric Aspects of Pregnancy—Pregnancy and the puerperium consume a year of the individual's life, and this in itself is of psychiatric significance. Considering the complexities of our culture, pregnancy, labor and the postpartum period have major psychiatric implications and, as Piker⁸ points out, the obstetrician can no longer confine his

attention to the "pelvic outlet" but must evaluate the total personality of the patient, as experienced obstetricians always have.

The Normal Woman and Pregnancy—Many normal women have apprehension regarding the danger of pregnancy and labor, and concerning the child-to-be. These fears are usually based on misinformation and superstitions acquired earlier in life. Under ordinary circumstances a brief superficial discussion will allay the patient's tension. If the obstetrician becomes aware of considerable tension on the part of the patient she should be permitted to unload her various ideas and be guided by explanation and encouragement to dissipate the tension if not the ideational content. The mere fact that the patient feels that the physician is attentive, sympathetic and reassuring will go a long way to reduce her emotional tension.

The normal woman may not want a child or additional children for many reasons and when confronted with pregnancy, may become tense and resentful. The situation may be further complicated by unsuccessful attempts at abortion and fears about the ill effects on the offspring. Most of these cases react favorably to common sense guidance by the psychiatrically minded obstetrician.

The Psychoneurotic Woman and Pregnancy—Women are often advised to become pregnant in order to improve their psychoneurotic state. This as a rule is poor advice. It is a clinical fact that during pregnancy especially after the first weeks, the psychoneurotic feels at her best. As a rule, however, the added responsibility of the offspring, in the inadequately treated psychoneurotic, causes a marked exacerbation of symptoms. The much better plan is to treat the psychoneurotic first and long enough for her to procure a good insight into her neurotic problems so that she feels the urge to give enough of herself to have a child and assume the responsibility that goes with motherhood. This is especially true of women whose marriage was delayed for years by phobias, compulsions and obsessions. In these women the desire to have an offspring is an indication of satisfactory progress in psychotherapy and indicative of satisfactory adjustment in many phases of their lives.

In the majority of psychiatrically untreated cases, the psychoneurotic condition becomes worse with pregnancy. To begin with, in many cases the pregnancy is unwanted, consciously or otherwise. There are many conscious reasons for this attitude: illegitimate pregnancy, fear of disfigurement, fear of forthcoming responsibility, fear of being made to give care to the home and children, economic factors and many more understandable situations. In many cases the child is not wanted for unconscious reasons, although overtly the anxiety to avoid pregnancy is subtly masked by pretense to have an offspring. The fear or resentment of pregnancy in these cases is traceable on the one hand to the constitutional factors of the neurosis, especially phobic and compulsive-obsessive tendencies, and, on the other hand to situa-

for transient delirium. Lastly, idiosyncrasies to drugs undoubtedly account for some transient delirious states.

In general, it may be stated that the organic type of reaction, if the cause can be removed, is of relatively brief duration and the recovery is complete. If the cause is removed and the mental disturbance persists, it is reasonable to assume that there is a constitutional factor responsible for the psychotic reaction.

The *manic-depressive* reactions are most commonly encountered. The onset of the psychosis is usually between the first and fourteenth day postpartum, although in some cases the symptoms may be evident before delivery or may not appear for weeks after delivery. The onset may be sudden but is usually gradual. The patient exhibits some personality changes with increase in tension, undue anxiety, restlessness, irritability, disturbances of sleep and more particularly changes in mood. The condition then develops into either a depression, often masked by somatic complaints (Denison and Yaskin¹²), or into a manic phase. In the depressed patients suicidal ideas and actual attempts at suicide are not uncommon. In the manic phase, overtalkativeness and often harmfully poor judgment are exhibited.

In the *schizophrenic reaction* the time and mode of onset may be the same as in the manic-depressive. Here the personality changes may be even more marked with considerable general discontent, marked tension and apprehension and other mood changes. But in addition, there often are present suspiciousness, tendency to misinterpretation, phobias, hallucinations and infanticidal ideas.

The *predisposing causes* of the various types of psychoses are to be found first and foremost in the personality make-up. The *exciting causes* in the relatively infrequent organic type of reaction are found in the various conditions above enumerated. Among the exciting factors in the manic-depressive and schizophrenic reactions, the following may be mentioned: long-continued economic stress, incompatibility between marital partners, undesired pregnancy, a feeling of inadequacy about the responsibility of motherhood, and a previously sheltered life (Ordway and McIntire¹³).

The *prognosis* of the postpartum psychosis varies with the type. Recovery is complete in the organic cases which survive the underlying physical factors. The manic-depressive patients recover if they do not commit suicide or succumb to intercurrent disease, but recurrences are quite common with or without subsequent pregnancies, perhaps more so with subsequent pregnancies. The prognosis in the schizophrenic group is unfavorable. Social recovery occurs in only 15 to 30 per cent of cases and the likelihood of exacerbation of the process is great with subsequent pregnancies.

The *treatment* of the postpartum psychosis does not vary from other types of psychotic reactions. In the organic type the early recognition of the physical factors is of great importance since the recovery in

these cases depends largely on the removal of these factors. Careful physical examination and laboratory studies should be performed on every patient who develops psychotic reactions after childbirth. In the presence of a delirium, repeated studies should be performed. Temperature readings and complete blood counts are often helpful in doubtful cases.

Early diagnosis of schizophrenia and especially manic-depressive reactions is highly desirable. The obstetrician who knows the personality make up of his patient for months prior to delivery is in excellent position to recognize the early symptoms and be instrumental in starting early treatment. This is particularly important in cases exhibiting suicidal and infanticidal tendencies.

The depressed patient is to be particularly guarded because of the danger of suicide. Moreover, the more severe types of depression are readily amenable to electrocerebral shock therapy which may be commenced about four to six weeks after delivery. With this form of treatment about 60 per cent of the cases make complete recovery within four to six weeks. Those which do not respond last from six to nine months. The manic patient recovers spontaneously in six to nine months and is less amenable to shock therapy, which should be reserved for very severe manic patients.

The treatment of the schizophrenic patient is less satisfactory. In some cases insulin shock therapy is used.

Psychotherapy has its place in the treatment of the psychoses but compared with the shock forms of treatment or with its efficacy in the psychoneuroses it is of less value.

The Problem of Termination of Pregnancy—The question of termination of pregnancy in one who has had a psychosis in the postpartum period and the whole matter of contraception and sterilization for therapeutic purposes is so entangled in popular and religious attitudes, as well as in its medicolegal complications and the problems concerning hereditary transmission, that it cannot be settled at present. Generally speaking, however, it would not seem advisable for a woman who has had a psychosis following childbirth to have more children since another childbirth might well precipitate another psychotic episode or activate a quiescent psychosis (Cohen¹⁴). Yet, in my experience, women who have had manic-depressive episodes following childbirth have had one, two and three children thereafter without psychotic reactions and at least one woman who had a schizophrenic reaction after the birth of the second child had two subsequent pregnancies without mental disturbance.

SOME PSYCHIATRIC ASPECTS IN GYNECOLOGY

Menstrual Disturbances—There are many psychological aspects to menstruation. Chadwick,¹⁵ in her monograph on the Psychological Effects of Menstruation, indicates convincingly that all races have shown

guilt over menstruation and according to their folklore they have needed some impersonal or plausible way to explain its occurrence. The ancient idea that the monthly flow of blood was accompanied by cruel and hostile wishes within the woman led to many taboos erected against her, as is well portrayed in the Old Testament. The psychiatrist often sees it in our own culture, through phantasies, anxieties, superstitions and hostilities in the individual patient. These psychological factors may be overt or may be highly symbolized.

Dysmenorrhea—The experienced gynecologist has learned that many cases of dysmenorrhea are functional, that is, not due to any discernible organic or biochemical causes. He learned by experience to avoid useless operative procedures. Functional dysmenorrhea may be one of the many manifestations of the neurotic make-up or, like migraine, a monosymptomatic manifestation of a deep-seated neurosis. Wengraf¹⁶ considers functional dysmenorrhea as an organ neurosis exhibiting the following characteristics: (1) absence of demonstrable pathology, (2) inconstancy, the pain varying from month to month, mostly as a reaction to pleasant or distressing events, (3) reversibility, (4) connection with neurotic symptoms, (5) amenability to diverse therapy, and (6) amenability to suggestion and hypnosis. Menstruation becomes the realization of old guilt feelings directed particularly toward the mother. Dysmenorrhea manifests suppression and conversion symptoms. It may be exhibited in three spheres: local, including backache and urinary or rectal disturbance, general complaints involving the cerebrum and/or abdominal and secondary sexual organs, and psychosexual. Frigidity is a frequent accompaniment. Cessation of menstrual cramps, if the psychogenic factors remain, may mean only that the neurosis is finding expression in another form. Kroger and Freed¹⁷ have cured dysmenorrhea by hypnosis. While these authors are perhaps unique in pioneering in their views, there can be little doubt that some cases of functional dysmenorrhea may be favorably influenced by judicious psychotherapy. Here, as in other psychosomatic situations, simpler methods should be resorted to prior to plunging the patient into time-consuming expensive, psychological procedures.

Amenorrhea—Amenorrhea as a psychiatric problem has received little attention in the literature. Although not relevant to the subject I should like to stress that amenorrhea may antedate other evidences of a pituitary tumor by months or years. Amenorrhea is not uncommonly due to major emotional disturbances and is particularly common in the major psychoses such as depressions and schizophrenic reactions. It may be the earliest clinical manifestation of a beginning psychosis.

I should like to stress that the amenorrhea of the psychoses has no etiological significance and that the patient need not be subjected to therapy to bring on the menstrual flow. With recovery from the psychosis, menstruation becomes reestablished.

Sterility—The psychological study of sterility in women has thus far received little attention. It has long been observed that conception may occur in a previously sterile woman after she has adopted a child. Bear¹⁸ discusses this problem and expresses the opinion that following the adoption of a child some change in the mode of life situation, but without discernible changes in their structure or physiology, follows, and conception takes place. He urges psychiatric studies in cases of sterility in which no satisfactory gynecological causes for the sterility can be found.

Frigidity.—Varying degrees of frigidity are quite common and are important from a psychiatric standpoint. While frigidity in itself is not a serious "symptom" it often becomes the cause of marital disharmony. Frigidity in the psychoneurotic is of great prognostic importance, and the woman who remains frigid after treatment usually makes unsatisfactory improvement.

Weiss and English¹⁹ classify frigidity into the following grades: occasional failure to achieve orgasm, only occasional orgasm, mild pleasure in intercourse but no orgasm, vaginal anesthesia with no special aversion to coitus, vaginal anesthesia with aversion to coitus, and dyspareunia and vaginismus.

They suggest the following causes for frigidity: fear of disapproval or punishment, hostility toward the partner, conflicting loves (usually unconscious), latent homosexuality, and too much self-love.

In the treatment of the various grades of frigidity, it should not be forgotten that many cases are due to organic conditions, including organic disease of the nervous system and the endocrine apparatus. However, every psychiatrist knows the role of frigidity in the structure of the psychoneuroses and realizes that in the course of psychotherapy many causative factors come to consciousness and that with the improvement of the psychoneurosis the frigidity becomes less marked or disappears altogether.

I should like to stress that in depressions, especially in the manic-depressive depressions, frigidity is an early and constant symptom. With the disappearance of the depression, normal sexual attitudes and reactions become reestablished.

Sexual perversions have many psychiatric aspects and at the present time are of little gynecologic interest. Nymphomaniacs, homosexuals, exhibitionists and the like remain, for the present, largely psychiatric and social problems.

Psychiatric Aspects of Gynecologic Surgery—The psychiatric aspects of gynecologic surgery do not differ from the other forms of surgery, especially abdominal surgery, and will be dealt with briefly.

Both surgeon and psychiatrist have long since learned that organic pelvic disease is not a cause for either neurosis or psychosis. The experienced surgeon is keenly aware of the fact that avoidable or elective surgery does not improve the psychoneurotic. He has learned to

caution the neurotic in advising a necessary operation, such as removal of an ovarian cyst or repair of the pelvic floor, that it will have no, or no material, influence on the course of her neurosis. Indeed he learns by experience to have psychiatric guidance when confronted with operations of necessity in severe psychoneurotic states. A promise that a pelvic or abdominal operation will cure a neurosis is due either to dishonesty, lack of knowledge and experience, or both, and is not conducive to benefit to the patient, and, in the long run, to the surgeon.

Surgical procedures in themselves do not produce neuroses or psychoses. Some psychoneurotics are temporarily benefited by the rest, attention and regimen incident to surgical procedures. Many of these patients have an exacerbation of their neurotic symptoms following the surgical convalescence, when confronted with old responsibilities and a return to their faulty attitudes and reactions.

The psychoses that follow surgical procedures are basically the same as those following childbirth, with one exception, that gynecologic procedures in later life are at times followed by presenile, senile and arteriosclerotic dementias and by involution melancholia. In addition to the above-mentioned organic types there are the organic reactions incident to sepsis, hemorrhage, intoxications and exhaustive factors. By far more common, however, are the manic-depressive and schizophrenic reactions, in which cases the operative procedure is merely a precipitating cause in a constitutionally predisposed individual.

Involution Melancholia—This is a psychosis occurring most commonly between the ages of 45 and 55, about three times more common in women than men, often beginning with somatic complaints, referable most commonly to the abdominal organs, associated with or followed by depression, agitation, delusions of self-accusation, but occasionally paranoid trends, suicidal tendencies and other severe psychotic reactions.

It occurs most commonly in the rigid type of individual, described earlier in this paper. There is no evidence, at present, of any definite structural or biochemical cause for this disease. Despite the voluminous literature to the contrary, I am convinced that involution melancholia has no etiologic relation to the endocrine changes of the menopause, although I do not deny the probability that there may be biochemical factors for this disease and most of the other psychoses.

Prior to the advent of shock therapy, the prognosis of involution melancholia was unfavorable, not more than 50 per cent recovering in from two to four years.

The treatment of involution melancholia, in the absence of contraindications, is electrocerebral shock therapy. From 80 to 90 per cent of these cases recover within a few weeks. The gynecologist can be of great service in suspecting the disease early in its course and thus help to avoid suffering, invalidism, and often suicide. The endocrine

substances may alleviate the flashes and other vasomotor phenomena but do not cure involution melancholia.

SUMMARY AND CONCLUSIONS

Modern clinical medicine and surgery must take into account the psychological aspects in many problems. To do so the clinician should learn to think systematically in terms of personality make-up, personality types and reaction types. He should possess a few definite principles in psychotherapy and allied suitable methods of treating psychiatric problems. With this in mind, useful psychopathology and psychotherapy were briefly discussed.

The obstetric and gynecologic problems have many psychiatric aspects which hitherto have received too little attention.

The psychiatric problems of pregnancy were discussed from the standpoint of the psychoneurotic and with special reference to the vomiting of pregnancy. The psychotherapy of the psychoneurotic prior to conception, during pregnancy and postpartum, were discussed. The concept of a special puerperal psychosis is no longer tenable. The psychotic reactions following pregnancy are usually manic-depressive or schizophrenic. The organic type of reaction is uncommon but when present should receive careful attention in order to remove the underlying physical causes.

Many gynecologic problems have definite psychiatric aspects. Those briefly discussed include dysmenorrhea, amenorrhea, sterility, frigidity and gynecologic surgery.

Involution melancholia is of particularly great interest to the gynecologist and early diagnosis and treatment were stressed.

One 3-ounce bottle of fluidextract of ergot
 Four abdominal binders
 Four breast binders
 Sterile boric acid solution, 1 pint

The next important step is the *selection of the room*. A room which is well lighted, airy, and convenient to lavatory facilities should be selected for the delivery of the patient.

The room should be as spacious as possible and all unnecessary furniture should be removed. All that is necessary is a bed with a firm spring, a bureau, a few straight chairs, and two tables for the reception of those articles which are needed in the conduct of labor and the puerperium.

Fig 187—Contents of obstetrical bag (From "Mechanics of Obstetrics" by Vaux and Castallo, F A Davis Co)

As the time of delivery approaches all the furniture should be carefully protected by ample layers of newspapers. The floor around the bed should also be covered with layers of newspaper, and a bucket or basin placed on the floor, at the side of the bed, for the disposal of waste material.

The next important step is the *preparation of the bed*. A narrow bed with firm springs and firm mattress is best adapted to the conduct of labor. If this is not available and the spring sags, an ironing board or extra table leaves should be placed either under the springs or between the springs and the mattress. This is to prevent the accumulation of blood and amniotic fluid in a pool in the center of the bed during the delivery.

A rubber sheet should be placed directly over the mattress, or if one is not available, thick pads of newspapers should be employed to protect the mattress. A linen sheet is placed over the papers or rubber sheeting. During the actual delivery, a Kelly pad is so placed under the patient's buttock as to drain over the side of the bed into a bucket on the floor.

Preparation must be made before labor for the proper care of the baby. A large basket, bassinet or bureau drawer made comfortable with blankets, should be put in one corner of the room. At the onset of labor, a warm bottle should be placed in the blankets to warm them for the newborn child.

Fig 188—Showing arrangement for delivery in small room. 1 Bed surrounded by newspaper to protect floor. 2 Bucket for disposal of waste, secundines, etc. 3 Basin of lysol. 4 Table of solutions, instruments, etc. 5 Chair. 6. Windows. (From "Mechanics of Obstetrics" by Vaux and Castallo, F. A. Davis Co.)

During the first stage of labor when the patient is first seen a careful and complete examination should be made. This should cover the patient's general condition, i.e., (1) general appearance, (2) temperature, (3) pulse, (4) respiration, (5) blood pressure, (6) palpitation and auscultation of the heart. Then a determination is made, by a careful abdominal and rectal examination, of attitude, presentation and status of the fetus and the degree of advancement of labor.

There is probably no point which means more to the patient than this careful initial examination on the part of the obstetrician and his assurance that all is well. By this single act, her confidence is gained. No sedative or analgesics can take the place of this.

As soon as labor is started an ample quantity of water should be put to boil in three large containers. One is allowed to cool after boiling for thirty minutes, the second should be kept warm after having boiled for a similar period, and in the third, the enamel basins and pitcher should be sterilized. Hot and cold sterile water are thus made readily available for use during labor.

The instruments should be sterilized by boiling in the special copper container carried in the obstetrical bag. After the water is drained, this container should be kept covered until the time of delivery.

Preparation of the patient is done at this time. Her hips are elevated on a bed pan. A sterile cotton sponge moistened with lysol solution is inserted in the introitus to prevent the entrance of infective material. The adjacent parts are then washed with a solution of green soap and lysol.

The pubic and vulvar hair is then shaved from above downward. When all the hair has been removed, the pubis, vulva, perineum, and inner margins of the thighs are thoroughly scrubbed with a solution of green soap and lysol, using sterile gauze or cotton.

The bladder should be catheterized only when its distention is such that it interferes with the mechanism of labor. If the rectum is distended with fecal material, a low enema should be administered before the perineum and vulva are prepared.

First Stage of Labor—During the first stage of labor in normal presentation the patient may walk about freely or sit in a chair. She is encouraged to take nourishment which is readily assimilated, such as various forms of carbohydrates, fluids in the form of water, weak tea with sugar, fruit juice or ginger ale. The patient should be cautioned against endeavoring to "bear down" with the pains of the first stage.

Second Stage—During the second stage of labor, the obstetrician should be in constant attendance upon the patient, or within ready call. Abdominal examination should be repeated at frequent intervals to determine the strength and frequency of labor pain, degree of descent of present part and condition of fetal heart sounds. Rectal examination should be frequently done to confirm the station of the presenting part and determine the degree of dilatation of the cervix. Vaginal examination is to be employed only under special indications.

FINAL PREPARATION FOR DELIVERY

In the case of a multiparous patient, preparations for delivery are made when the pains become of a bearing-down character and the cervix is from 4 fingerbreadths to completely dilated.

In the case of a primigravida, preparations for delivery are made when bulging of the perineum is noted.

The physician's outer clothing and shoes should be replaced by an operating shirt, trousers and shoes. His hands must be scrubbed for

ten minutes, preferably under running water. They should then be immersed in 70 per cent alcohol solution. A sterile gown and sterile gloves are put on.

The patient is placed in bed in the dorsal posture with a sterile square of linen on her abdomen and one beneath her hips. The inner side of the thighs, vulva and perineum are cleansed with green soap and lysol solution. A sterile sheet is placed on the lower half of the bed and a similar sheet across the abdomen. The patient's lower extremities are ensheathed in leg covers.

The instruments and solutions are arranged on tables near the foot of the bed. The preparations are now complete for the actual birth of the child.

DELIVERY OF THE CHILD

In spontaneous labor it is best to let the patient's feet rest on the surface of the bed until delivery. Then she is placed across the bed with legs over the back of chairs so that she may have some anchorage during her pains and until delivery is consummated.

Fig. 189—Disengaging the cord from about the baby's neck. ("Mechanics of Obstetrics" by Vaux and Castallo F. A. Davis Co.)

As the presenting part distends the vulva, care should be taken to avoid extensive lacerations, by placing one hand against the fetal head to restrain it from too rapid expulsion across the perineum. The other hand is employed to lift the head over the perineum by the "maneuver."

When the head of the baby is born, the mucus and amnion are wiped from the nose and mouth and the neck is freed

The patient's lower extremities are ensheathed in leg covers.

The instruments and solutions are arranged on tables near the foot of the bed. The preparations are now complete for the actual birth of the child.

DELIVERY OF THE CHILD

In spontaneous labor it is best to let the patient's feet rest on the surface of the bed until delivery. Then she is placed across the bed with legs over the back of chairs so that she may have some anchorage during her pains and until delivery is consummated.

Fig. 189—Disengaging the cord from about the baby's neck. ("Mechanics of Obstetrics" by Vaux and Castallo F. A. Davis Co.)

As the presenting part distends the vulva, care should be taken to avoid extensive lacerations, by placing one hand against the fetal head to restrain it from too rapid expulsion across the perineum. The other hand is employed to lift the head over the perineum by the Ritgen maneuver.

When the head of the baby is born, the mucus and amniotic fluid are wiped from the nose and mouth and the neck is freed from the

restraints of the encircling coils of the umbilical cord. Generally the cord can be slipped over the baby's head (Fig 189). If this fails, however, the cord may be slipped back over the shoulders during birth. If the cord is too tight for either maneuver, it may be cut between hemostatic clamps.

Haste should not be employed in the delivery of the shoulders, the latter are generally expelled spontaneously. If expulsion of the shoulders is unduly delayed, the fingers may be hooked over the fetal head, and steady, firm traction exerted posteriorly in order to bring the

Fig 190—Method of drawing down the anterior shoulder beneath the symphysis pubis ("Mechanics of Obstetrics" by Vaux and Castallo, F. A. Davis Co.)

anterior fetal shoulder under the symphysis pubis (Fig 190). The fetal head is then drawn anteriorly to deliver the posterior shoulder across the pelvic floor and perineum (Fig 191).

After the complete expulsion of the child, the attendant waits until pulsation of the cord has stopped. During this interval the baby should be held by the ankles with head dependent, in order to drain fluid from the respiratory tract. The free hand of the operator may be employed to gently "milk" fluid from the trachea.

The hand of the operator or of an assistant should be placed fre-

quently upon the maternal abdomen to make sure that the uterus becomes properly retracted around the placenta, and to note changes in contour which subsequently take place.

Fig 191—Method of delivering the posterior shoulder across the perineum after the anterior shoulder has been impinged under the pubis. ("Mechanics of Obstetrics" by Vaux and Castallo F. A. Davis Co)

CARE OF THE BABY

When the pulsation of the cord has ceased, two hemostatic clamps are applied, one 2 inches from the navel of the baby and the other a half inch distal to it. With the hand interposed as a protection between the fetal body and the scissors, the cord is cut between clamps. Two ligatures of cotton tape are applied and tied firmly, the first 1 inch from the baby's navel and the second in the groove formed by the proximal hemostatic clamp. A sterile dressing moistened with 70 per cent alcohol is applied to the stump of the cord. The dressing is held in place by a band of sterile gauze.

The obstetrician must assure himself that the air passages of the child are clear. This is accomplished first, by holding the child dependent by the legs and gently milking the trachea; second, by employing a suction apparatus or tube to draw fluid or mucus from the pharyngeal region of the baby; third, by inserting, in extreme cases,

a small silk intratracheal catheter and withdrawing plugs of mucus from the trachea (Fig 192)

Treatment of the Eyes—The baby's eyes should be treated as soon after delivery as possible. If the obstetrician has assistance, he may do this while he is waiting for the delivery of the placenta. Each eye

Fig 192—Aspiration of pharyngeal mucus in the newborn ("Mechanics of Obstetrics" by Vaux and Castallo, F A Davis Co)

should receive one or two drops of 1 per cent fresh solution of silver nitrate (1 per cent silver acetate also is used) into the conjunctival sac (Figs 193 and 194). Care must be taken that the eyelids of the baby be sufficiently separated for the silver nitrate to actually enter the sac. An eyelid retractor, such as the Castallo, may be used. After two or

three minutes, the excess of silver nitrate is flushed out with physiologic salt solution. This final step lessens the incidence of chemical conjunctivitis.

Fig 193—Perforating a wax ampule in preparation for the Credé prophylactic treatment of the newborn's eyes ("Mechanics of Obstetrics" by Vaux and Castallo, F. A. Davis Co.)

The physician, having assured himself that air passages of the child are clear and the eyes treated, wraps the child in a warm sterile towel, or a square of sterile linen, and the child is placed in its warm crib.

Fig 194—Showing method of instilling silver nitrate solution in infant's eyes from paraffin capsule. ("Mechanics of Obstetrics" by Vaux and Castallo F. A. Davis Co.)

MANAGEMENT OF THE THIRD STAGE OF LABOR

Throughout the period of attending to the baby after its delivery, either the obstetrician or a competent assistant must make frequent observations of the condition of the uterus and the amount of bloody discharge from the vagina. Occasionally, partial detachment of the placenta will give rise to constant and severe vaginal bleeding, which necessitates the obstetrician's undivided attention.

The mechanism of separation of the placenta should not be rushed, but when the placenta has separated and lies in the lower segment of the uterus and in the vagina, its expulsion may be accelerated. The separation of the placenta can be recognized by changes in the contour and the station of the fundus, bloody discharge from the vagina and advancement of the umbilical cord.

When these signs are present, the placenta may be expelled from the birth canal by exerting manual pressure backward against the contracted uterus. In other words, by using the contracted and empty

organ as a piston (Fig 195), the placenta is forced out of the lower birth canal. As the mass of the placenta is expelled from the vagina, it should be turned over and over so that the membranes are rolled into a rope and drawn down complete from the uterine cavity (Fig 196). Placenta and membranes are collected in a basin held beneath the vaginal outlet with one hand while the other remains free for exerting pressure on the fundus.

Fig 195—Expression of the placenta by pressure on the fundus ("Mechanics of Obstetrics" by Vaux and Castallo, F A Davis Co)

When the placenta has been delivered the hand of the obstetrician placed upon the maternal abdomen should follow the uterus down toward the pelvis and by vigorous massage insure that the uterus remains firmly contracted, thus avoiding excessive blood loss. This is followed by administering an oxytocic drug such as ergot, ergotrate or extract of posterior lobe pituitary or its derivatives.

Inspection of the Placenta—The next duty of the obstetrician is to examine the placenta and membranes to make sure that no portion is retained in the cavity of the uterus. This examination is accomplished by laying the placenta upon a table and carefully inspecting the maternal and fetal surfaces.

The maternal surface should present a composite and complete picture. The cotyledons should fit snugly against one another and the margin should be smoothly leveled off throughout the circumference. Upon the fetal surface the large branches of the umbilical vessels should be traceable to intact segments of the placental tissues. A large vessel torn off at the margin of the placenta or one which leads beyond the margin to a raw area on the membranes, indicates that a

Fig 196—Method of extracting the membranes by rotating the placenta. ('Mechanics of Obstetrics' by Vaux and Castallo F. A. Davis Co)

placenta "succenturiata" has been detached and retained in the uterine cavity.

The membranes should be examined to see if they are complete. Retention of membranes generally does no harm. Retained portions of placenta, however, should be removed, for they will give rise to postpartum hemorrhage and puerperal infections.

Inspection for Lacerations—After the operator is sure that the expulsion of the placenta is complete, the lower birth canal is examined for laceration. If labor has been spontaneous and uncomplicated, the cervix should not be inspected. If there are any lacerations of the perineum they should be immediately repaired unless the condition of the patient contraindicates anesthesia and manipulation.

ANALGESIA AND ANESTHESIA, FORCEPS

Analgesia—The following analgesics may be used at home demerol, 100 mg, and $\frac{1}{150}$ grain of scopolamine intramuscularly when the patient is having labor pains every three to five minutes lasting twenty to thirty seconds. If after one or two hours the analgesic effects appear to be wearing off, another dose of 100 mg of demerol intramuscularly is given. The scopolamine is repeated with demerol at four-hour intervals, but each subsequent dose of scopolamine is half of the previous dose. There is usually much relief of pain and partial amnesia. The patient will sleep between pains.

Another satisfactory analgesic agent is the combination of 3 grains of seconal by mouth and 1 grain of codeine sulfate intramuscularly. This combination usually gives good results with multiparous patients. If the patient develops hallucinations or excitability from either combination, open drop ether can be used to control her until she can be given rectal ether.

If neither of the above combinations gives good results, rectal ether may be employed. First a cleansing enema is given, then a rectal tube is passed to a point above the presenting part, if the presenting part is low. Two ounces of warm mineral oil is then instilled to protect the rectal mucosa, and this is followed by 2 ounces of ether. Finally 2 ounces of warm mineral oil is instilled to clear the rectal tube. The tube is removed and the gluteal cheeks are held together to aid the patient in retaining the enema. When ether is detectable on the breath of the patient it is a sign that the ether has been absorbed and the patient most likely will not expel the mixture. The results with rectal ether following one of the above combinations or as the sole agent are very often satisfactory.

Anesthesia—The only safe anesthetic for use at home is dropped ether. It is easily administered by anyone and the doctor can watch the effects as he is doing the delivery. Spinal and caudal anesthesia are contraindicated for use in home deliveries.

Forceps—The use of inlet or midplane forceps is a procedure for hospitals where there are proper supervision and facilities for the handling of any emergencies that might arise. There is no contraindication to the use of outlet forceps in the home if the doctor knows the indications and contraindications therefor.

COMPLICATIONS OF LABOR

Abnormal Presentations—Whenever the doctor suspects or diagnoses an abnormal presentation such as breech, transverse lie or disproportion, the patient is admitted to the hospital. Good prenatal care and adequate attention to the patient during the early stages of labor will create opportunities for diagnosing the condition in time to get the patient to the hospital for the delivery.

Postpartum Hemorrhage—This complication is not common in our home deliveries. If excess bleeding is noticed, Credé's method is employed if the placenta has not been expelled. The uterus is lifted out of the pelvis. One hand placed above the symphysis pubis applies pressure towards the promontory of the sacrum and the other hand on the fundus applies pressure toward the symphysis. This brings the uterus under control while active measures are being provided.

Pituitrin and ergotamine tartrate are given intramuscularly. Then one ampule of ergotamine tartrate is given intravenously. The ambulance is sent with blood plasma, which the patient receives. The uterus is packed if it has not responded to oxytocic drugs. The patient is removed to the hospital, where further treatment for hemorrhage is administered.

Infections.—Some patients will be found with a septic temperature, due to the fact that they have had intercourse the night before going into labor. A mild *endometritis* develops. The endometritis at times becomes more severe. The patient develops a painful uterus and tenderness in the lower abdominal quadrants. Parametritis or pelvic cellulitis may develop. This condition responds favorably to sulfa therapy. The patient receives 2 gr of sulfadiazine or sulfathiazole, then 1 gm every four hours with equal amounts of sodium bicarbonate. Penicillin, 100,000 to 200,000 Oxford units per twenty-four hours, is also given in combination with sulfa therapy, depending upon the severity of the infection. Fluids are forced to over 2000 cc each twenty-four hours. A blood specimen and a catheterized specimen of urine are taken and examined at the hospital.

Breast infections are treated immediately by resting the breast, and early sulfa therapy is instituted. If an abscess forms, the patient is admitted to the hospital and the abscess is incised and drained.

Pyelitis is another common infection which responds very well to sulfa therapy.

Breast infections are treated immediately by resting the breast, and patients who live in poorly heated homes and whose surroundings are not the best. The patient is placed on 4 gm of sulfadiazine as the initial dose, then 1 gm every four hours with equal amounts of sodium bicarbonate. Fluids are forced to at least 2000 cc for every twenty-four hours. If the patient does not respond to sulfadiazine, penicillin therapy is instituted. A blood count and an examination of a catheterized specimen of urine are made every forty-eight hours when sulfonamides are given.

SINGLE DOSE AND CONTINUOUS SPINAL ANESTHESIA FOR LABOR AND VAGINAL DELIVERY

MAHLON C HINEBAUGH, JR., M.D.* AND WARREN R LANG, M.D.†

SPINAL anesthesia was introduced in obstetrics by Kreis in 1900. Unfortunately, at this time cocaine was the only available anesthetic agent. Because of the marked toxicity of the drug, maternal mortality was high. As a result, the procedure met almost universal condemnation by the profession and it was soon abandoned. After a lapse of approximately twenty-five years interest in the method was revived. This was largely due to the development of new and less toxic drugs plus a more complete understanding of the physiology of spinal anesthesia and its mode of action. In 1930 Cosgrove¹ reported the first large series of cases delivered under spinal anesthesia. He was able to demonstrate that, when properly used, this type of anesthesia was relatively safe. Despite this favorable report, the reaction was by no means enthusiastic. The procedure continued to meet with violent opposition from many prominent obstetricians of the time. Its employment therefore continued to be restricted. During the period of 1930 to 1940 the use of spinal anesthesia for caesarean section became more widespread as its superiority over inhalation anesthetics became apparent. The introduction of continuous spinal anesthesia in 1940 by Lemmon² is to a considerable degree responsible for its present popularity.

ADVANTAGES AND DISADVANTAGES

A discussion of the advantages and disadvantages of any obstetrical anesthesia should be based on (1) safety to the mother, (2) safety to the infant, (3) its effectiveness and (4) ease of administration.

Spinal anesthesia is essentially a form of local nerve block. Its effectiveness depends upon the paralysis of sensory nerve impulses as they enter the spinal cord. The fact that the action of spinal anesthesia is limited anatomically is of prime importance in the consideration of its application to obstetrics. Briefly, this anatomic limitation is dependent upon such factors as the site of injection, the amount, concentration and specific gravity of the agent, position of the patient, and barbotage. It is therefore possible to block the sensory innervation of the uterus (D_{11} , D_{12}), cervix and lower birth canal (S_2 , S_3 , S_4), without producing paralysis of the motor fibers (D_6 and above). This permits uterine contractions to continue and at the same time afford

* Diplomate, American Board of Obstetrics and Gynecology, Demonstrator of Obstetrics, Jefferson Medical College, Assistant Obstetrician, Jefferson Medical College Hospital, Philadelphia

† Resident in Obstetrics and Gynecology, Jefferson Medical College Hospital

complete pain relief without materially interfering with the progress of labor. In addition, since the uterus retains its ability to contract firmly, the danger of atonic postpartum hemorrhage is greatly reduced. The complete relaxation of the pelvic floor and perineum incident to spinal anesthesia greatly facilitates certain operative procedures such as midforceps rotation and extraction.

Of considerable importance is the ability of the completely conscious patient to cooperate. Indeed, in a multipara painless spontaneous delivery can be accomplished by instructing her to "bear down" during the uterine contractions. Furthermore, there is no need to restrict fluids or food in the immediate postpartum period. This is in marked contrast to inhalation anesthetics. Throughout our experience with spinal anesthesia, particularly when using the continuous technic, we have been impressed by the fact that practically every woman is conscious of a deep emotional satisfaction in being awake during her delivery and seeing her child as soon as it is born. This accounts in a large measure for the marked enthusiasm of the patient for this method of pain relief. Of almost equal importance to the welfare of the mother is the necessity for safeguarding the infant. In this respect spinal anesthesia is unique. As we and others have pointed out in previous papers, spinal and continuous spinal anesthesia are without any adverse effect upon the fetus.^{2,4} Respiration is immediately established and cyanosis is absent.

In the main, the disadvantages of spinal anesthesia are minor in character. Those antagonistic to its use attempt to justify their position by simply stating that it is too dangerous for the pregnant woman. Careful analysis fails to substantiate this claim. For the most part, fatalities are due to such avoidable factors as (1) its selection in spite of contraindications, (2) errors in technic, and (3) its employment by unqualified individuals. In this connection it seems rather strange that physicians who would never think of administering chloroform or nitrous oxide to a patient will without any hesitation attempt to give a spinal anesthetic. Probably the greatest single disadvantage to spinal anesthesia is its limitation of applicability. It should never be used except in a well equipped institution and under the direction of a well trained anesthetist. Oxygen, vasopressor drugs, stimulants and intravenous fluids must be available for immediate use. Because of the high incidence of operative delivery spinal anesthesia is not suited for the untrained obstetrician. A small percentage of patients complain of headache following delivery, but this is in most instances readily controlled by ergotamine tartrate and aspirin.

INDICATIONS AND CONTRAINDICATIONS

Because its effect is restricted to a local area, spinal anesthesia is particularly indicated in the following conditions: (1) infections of the respiratory tract, whether acute or chronic; (2) certain types of heart

disease, (3) hypertensive toxemia, because of the reduction of blood pressure and vasodilatation resulting in increased urinary output, (4) prematurity, (5) previous cervical and vaginal plastics due to its relaxing effect on the lower genital tract

Spinal anesthesia is contraindicated in (1) severe anemia (vasodilatation of the lower extremities in the presence of decreased blood volume predisposes to anoxemia), (2) marked deformity of the spinal canal or disease of the spinal cord, (3) local infections at or near the site of injection, (4) marked obesity, (5) those emotionally unsuited, (6) when there is a history of sensitivity to the drug

Obstetrical contraindications pertinent to vaginal delivery are (1) placenta praevia (the relaxing effect of spinal anesthesia on the lower uterine segment may cause marked bleeding), (2) cephalo-pelvic disproportion, (3) nonengagement of the presenting part, (4) in the presence of known fetal deformity or intrauterine fetal death, (5) such operative procedures as internal podalic version and certain cases of breech decomposition and extraction

SINGLE DOSE SPINAL ANESTHESIA

Single dose spinal anesthesia has been employed with increasing frequency during the past ten years. Its use is restricted by virtue of the fact that there is a definite limitation of the duration of anesthesia. There is some variation in the duration of anesthesia dependent upon the anesthetic agent employed. At the present time there are three drugs in common use.

Procaine hydrochloride (novocaine) is more extensively used than any other local anesthetic and has survived the test of clinical trial. Its toxicity is approximately one-sixth that of cocaine. The injection of 50 mg, dissolved in 2 cc of spinal fluid, is usually sufficient to produce good relaxation. The average duration of anesthesia is forty minutes.

Pontocaine, a very popular anesthetic in general surgery, has a limited number of advocates for vaginal delivery. It produces a prolonged anesthesia which is advantageous. However, this advantage is more than offset by the fact that it is eight times as toxic as procaine. In our opinion this high toxicity unnecessarily increases the danger to the patient and we do not recommend it. For those who wish to employ this drug we suggest the administration of 5 mg dissolved in 10 per cent glucose.

Metycaine hydrochloride is in our experience the drug of choice. It possesses a low toxicity, is prompt and uniform in action, and relatively long lasting in its effect.⁵ We employ 1.5 per cent metycaine in Ringer's solution (15 mg/cc). The average dose is 30 to 45 mg or approximately three-fourths the dose of procaine.

The injection of any anesthetic agent into the subarachnoid space may produce systemic toxic effects. The most important of these toxic

reactions are (1) central nervous system excitation, (2) cardiorespiratory failure, (3) allergic phenomena, (4) a combination of several factors. Despite the fact that allergic reactions are rare, it is wise to question patients with regard to a history of sensitivity to local anesthesia. Skin reactions have been recommended but are probably of little value.

Technic.—There are certain prerequisites for the safe administration of single dose spinal anesthesia. In a nullipara, the cervix must be completely dilated and the presenting part at the level with the ischial spines or below. In other words, it should not be given until the patient is ready for delivery. In a multipara the anesthesia may be induced before the cervix is completely dilated if the patient is having second stage pains and the presenting part is in the midpelvis. When these conditions have been satisfied, the patient is removed to the delivery room. Her pulse and blood pressure are recorded. If these are within normal limits she is placed on either side in an attitude of complete flexion suitable for lumbar puncture. After thorough surgical preparation of the area, the skin overlying the third or fourth lumbar interspace is infiltrated with local anesthesia. This may be accomplished by using procaine ephedrine solution (1 cc ampule) or metycaine. The wheal should be small in order to avoid obliteration of the landmarks. A small gauge spinal needle (No. 22) is then inserted into the chosen interspace and a free drip of spinal fluid is obtained. If procaine hydrochloride is used, 2 cc. of spinal fluid are withdrawn in which to dissolve 50 mg. of the drug. When metycaine (1.5 per cent in Ringer's solution) is used there is no need to withdraw spinal fluid. The anesthetic is slowly injected without barbotage and the needle removed.

The patient is now placed in the lithotomy position and prepared for delivery. The pulse and blood pressure are checked at five-minute intervals during the first half hour and then every ten to fifteen minutes until she has completely reacted from the anesthesia. Should the systolic pressure fall below 90 mm. a vasopressor drug, such as ephedrine sulfate, grain $\frac{3}{4}$, is administered hypodermically. Throughout the actual delivery 100 per cent oxygen is given by mask. We wish to emphasize the use of oxygen during the delivery. It acts to prevent any material drop in blood pressure and offset any tendency of the anesthesia to produce cardiorespiratory depression.

CASE HISTORY.—Mrs. D. McK., white, aged 26 years, Para O. Gravid 1, was referred from the medical department for antenatal care and delivery. She had been under collapse therapy for pulmonary tuberculosis for the past two years. Antenatal course was uneventful. The onset of labor was at 10 A.M. with premature rupture of membranes. She was admitted to the hospital at 4 P.M. not in labor. Uterine contractions began at 8.30 P.M. Examination at this time revealed longitudinal lie, back to right, vertex presenting FHS 136 r/q toward flank, cervix uneffaced and undilated presenting part at ischial spines. Four hours later the

patient was quite active and labor was progressing normally Analgesia was secured by seconal, grains 3, and hyoscine, grain 1/150

At 7 A M on the following day the cervix was completely dilated, head station midpelvis, position ROT Because of the pulmonary complication it was deemed advisable to shorten the second stage and the patient was removed to the delivery room Fifty milligrams of procaine hydrochloride was injected through the third lumbar interspace The patient was prepared for delivery Vaginal examination verified the position Apparently as a result of relaxation incident to the spinal anesthesia plus continuation of uterine contractions, the head descended to the pelvic floor Delivery was accomplished by an easy rotation and extraction A wide mediolateral episiotomy was done because of the large head Following birth of the child the uterus contracted firmly with very slight blood loss The placenta separated almost immediately and was expressed by simple fundal pressure at the end of three minutes, following which the uterus again contracted firmly with the blood loss minimal

The patient reacted well following delivery, artificial pneumothorax was repeated on the first postpartum day and the patient's hospital course was entirely normal The labor and delivery were without adverse effect upon the pulmonary lesion

CONTINUOUS SPINAL ANESTHESIA

Continuous spinal anesthesia for labor and vaginal delivery was first instituted, to our knowledge, by one of us in January, 1944 Our investigation was initiated through a desire to avoid certain disadvantages of continuous caudal analgesia as described by Hingson and Edwards⁶ These disadvantages while primarily technical, are nevertheless of great importance clinically (1) It is more difficult to insert a needle properly into the caudal canal than to perform a successful lumbar puncture, (2) massive doses of anesthetic solution are necessary in caudal analgesia, whereas in continuous spinal one-twentieth to one-thirtieth of that dose produces the equivalent effect, (3) the danger of the inadvertent introduction of the needle into the subarachnoid space or a vein during caudal analgesia is ever present, (4) should any toxic reaction occur during caudal analgesia, the anesthetic cannot be withdrawn In all other respects the factors which govern the use of continuous caudal analgesia apply to continuous spinal anesthesia By virtue of the small dosage requirement of the latter, it is possible to produce analgesia (sensory loss without motor paralysis) during the later part of the first stage of labor and anesthesia during the second stage for delivery Throughout our experience with this method of pain relief, we have constantly endeavored to improve and simplify the technic We believe that our present method is the nearest approach to an ideal obstetrical anesthetic It provides complete pain relief without jeopardizing the welfare of mother or child³

Since continuous spinal anesthesia is instituted during the first stage of labor, the following requirements must be fulfilled (1) the patient must be in active labor and have reached a point where she is suffering severe pain, (2) the presenting part must be at a level with or below the ischial spines, (3) in a nullipara the cervix should be dilated

at least 6 cm., but 4 cm is sufficient in a multipara. Failure to satisfy these requirements can only result in prolongation or actual cessation of labor.

Technic—Continuous spinal anesthesia may be induced in either the labor or delivery room, depending upon individual preference. The patient is prepared for lumbar puncture following the technic used for single dose spinal anesthesia. We prefer the second or third lumbar interspace. A 2.5 or 3 inch malleable caudal needle, of the type used by Hingson and Edwards,⁶ is inserted into the chosen interspace and a free drip of spinal fluid is obtained. The back is then extended in order to fix the needle firmly. The needle is then connected by rubber tubing to a 10 cc. Luer-Lok syringe with cut-off valve containing 1.5 per cent metycaine in Ringer's solution. An initial dose of 15 mg (1 cc.) is slowly injected without barbotage. This dose is in most instances sufficient to produce complete relief of pain within five minutes. Additional injections of 15 mg are repeated at necessary intervals, usually thirty to forty minutes, to maintain analgesia.

For best results it is advisable to use a split mattress and place the patient on her back after the initial injection. This affords greater comfort to the patient and produces equal distribution of anesthesia. If a split mattress is not available the patient must remain on her side. In case of unilateral anesthesia turning the patient on the opposite side gives prompt relief.

The level of anesthesia is checked at frequent intervals and should not extend more than 2 or 3 cm above the umbilicus. Should the anesthesia level reach the xiphoid or above, paralysis of the motor fibers of the uterus will result in cessation of labor. The pulse, blood pressure and respirations are carefully watched throughout the duration of the anesthesia. The progress of labor is determined by the frequency, force and duration of uterine contractions, increase in cervical dilatation and descent of the presenting part. We rely on rectal examinations. The delivery is conducted in the usual manner. We routinely use outlet forceps combined with episiotomy. The third stage of labor is allowed to occur normally. In most instances the placenta separates promptly and may be expressed by simple fundal pressure within five minutes.

Following completion of the third stage 1 cc. of pituitrin is administered. Under no circumstances should an oxytocic be given before removal of the placenta. Failure to observe this precaution will result in retention of the placenta for a number of hours. It must be remembered that spinal anesthesia does not interfere with the ability of the uterus to contract. Repair of the episiotomy is then carried out. We have noted a slight increase in the amount of bleeding from the incised perineum. This is due to vasodilatation incident to spinal anesthesia. The needle is not removed until repair of the episiotomy has been completed. If desired, prompt restoration of sensation may be

established by withdrawing a small amount of spinal fluid containing the anesthetic solution

CASE HISTORY—E. P., white, aged 27 years, Para O Gravida I Antepartum course was normal until the thirty-second week, at which time she developed hypertension (140/90), albuminuria and edema. She was admitted to the hospital. Her toxemia was brought under control and she was discharged at the end of one week with the diagnosis of mild preeclampsia. She was readmitted in active labor at 1:30 P.M. On admission the blood pressure was 140/90, no edema was present and the urine showed a plus 1 albumin. Uterine contractions were recurring at five-minute intervals, duration forty seconds, back to left, FHS 140 11q, cervix completely effaced and 2 cm dilated, vertex presenting, station midpelvis, position LOA. To secure preliminary analgesia, demerol 100 mg intravenously and scopolamine grain 1/150 intramuscularly were administered with good effect.

At 12:30 A.M. on the following day the cervix was 6 cm dilated, head station unchanged, uterine contractions every three minutes, duration fifty seconds. Continuous spinal anesthesia was induced with metycaïne, the initial dose being 15 mg. During the next two hours, the patient experienced no pain. There was a gradual drop in blood pressure to 120/80. At 2:30 A.M. rectal examination revealed complete cervical dilatation with head on the pelvic floor. Up to the time of delivery a total of 60 mg of metycaïne was injected. The delivery was completed by outlet forceps with a left mediolateral episiotomy.

Following delivery of the child the uterus contracted firmly. The placenta separated promptly and was expressed at the end of five minutes by simple fundal pressure. The uterus again contracted firmly and blood loss was minimal. The infant cried immediately and there was no cyanosis. Primary repair of the episiotomy was then carried out. The puerperal course was entirely normal and the patient was discharged on the tenth postpartum day.

SUMMARY

There are certain disadvantages of single dose spinal anesthesia which are overcome by the use of the continuous technic. These disadvantages are, as pointed out by Lemmon⁷ (1) failure of the single dose to produce the level and degree of anesthesia desired, (2) failure of the anesthesia to last for the length of time required to perform the procedure, (3) the inability to remove the anesthetic agent should any toxic reaction occur. The ability to immediately withdraw spinal fluid containing the anesthetic solution in the event of any toxic symptoms affords a safety factor which is of vital importance. An evaluation of the two technics, based upon extensive experience with each, leaves no doubt in our minds as to the overwhelming superiority of the continuous method. The administration of any anesthetic for delivery involves a certain element of risk. We firmly believe that continuous spinal, properly used, affords greater safety to both mother and child than any other method at the present time. Finally, it seems to us unnecessary to produce a general state of anesthesia when only local analgesia is required.

SOME RECENT LABORATORY PROCEDURES OF IMPORTANCE IN OBSTETRICS AND GYNECOLOGY

(Rh Test; Vaginal Smears for Ovarian Function and Uterine
Cancer; New Tests for Pregnancy)

A. E. RAKOFF, M.D.*

THE RH FACTOR

ALTHOUGH the discovery of the Rh factor¹ is only five years old it has assumed a place of considerable importance in obstetric practice not only because of its significance in relationship to erythroblastosis foetalis and transfusion reactions² but because abnormalities in this factor can *potentially* involve up to 15 per cent of pregnancies.

The Rh factor is an antigenic substance commonly present in human red cells specifically distinct from the major blood factors, A and B, and also from the subtypes such M, N and P. The Rh agglutinin has also the property of greater activity at 37° C. than at lower temperatures and is therefore termed a "warm" agglutinin.

Individuals in whom this Rh agglutinin or factor is present are designated as "Rh positive" while those in whom it is absent are called "Rh negative." An Rh-negative individual can be stimulated to produce "Rh antibodies" (anti-Rh agglutinins) by the injection of Rh-positive red cells, such as may occur by blood transfusion or passage of Rh-positive red cells from the fetal circulation to the maternal circulation during pregnancy. In the latter event "isoimmunization" of the mother may occur. The anti-Rh agglutinins are present in the serum and may pass from the maternal circulation through the placenta to the fetus, destroying the fetal red cells and producing hemolytic anemia with its sequelae, erythroblastemia, jaundice and edema, giving rise to the various clinical manifestations of fetal erythroblastosis.

The Rh factor is inherited as a simple mendelian dominant characteristic independently of the major blood groups and the M-N types.³ By means of different anti-Rh sera it is now recognized that the Rh factor is antigenically and genetically complex, probably being carried by a series of allelic genes variously designated by different serologists.⁴ However, as pointed out by Levine,⁵ since 92 per cent of all Rh incompatibilities in the mothers of erythroblastotic infants can be

From the Departments of Obstetrics and Gynecology, the Endocrine Laboratory and Clinic, Jefferson Medical College and Hospital, Philadelphia.

* Director of the Endocrine Laboratory, Jefferson Hospital, Instructor in Gynecology, Assistant Demonstrator in Obstetrics, Jefferson Medical College.

detected with a single anti-Rh serum (anti-Rho), for usual clinical purposes one may recommend the simple genetic theory based on but a single antibody. The finer differences of the Rh factor and the rare instances of isoimmunization with other factors are best left to the serologic specialist.

It has been found by sampling of various population groups that approximately 85 per cent of all white women are Rh positive and 15 per cent are Rh negative. Among Negroes 5 per cent are found to be Rh negative, and only 1 per cent among the Chinese.⁶ Because of the high incidence of Rh-negative individuals, particularly in the white population routine "Rh testing" of prospective mothers has become the rule in many institutions. Since immunization may occur in women following transfusions, Rh testing has also been recommended before transfusing young girls and women in the childbearing period.

Test for Rh Typing—A satisfactory technic^{*} is as follows

- In a carefully cleaned small test tube (about 0.4×8 cm.)
 1. Wash cells three times with saline.
 2. Place 2 drops of anti Rh serum.
 3. Add 2 drops of fresh saline suspension (2 per cent) of red cells to be tested (This corresponds in color to that obtained by the addition of one drop of blood to 2 cc. of saline)
 4. Shake and place in water bath at 37° C for thirty minutes.
 5. Centrifuge for one minute at 400 R.P.M. and observe sedimented blood and shake gently
 6. Inspect grossly for clumping. Those clumped are Rh positive.
 7. Inspect microscopically (low power) all grossly negative. Only those negative microscopically are considered Rh negative. (A small drop for microscopic inspection may be easily removed from the test tube to a microscopic slide by means of a small glass rod)
 8. In all questionable instances check on original saline suspension of unknown cells be sure that these are even unagglutinated suspensions of red cells

In the event that a prospective mother is found to be Rh negative it becomes necessary to test her husband. If he is found to be Rh positive the potentiality of an Rh incompatibility arises, whereas if he is Rh negative no such difficulty will ordinarily occur since the fetus will be Rh negative. Although 12 to 13 per cent of all matings will be between Rh negative women and Rh positive men, fortunately only a small percentage of them will result in fetal erythroblastosis (0.1 per cent of all pregnancies) because of the following factors⁷

1. In those instances in which the Rh-positive father is heterozygous (i.e., he carries an Rh positive gene and an Rh negative gene) 50 per cent of the babies will be Rh negative. In certain cases it is possible for the serologic specialist to determine whether a given individual is homozygous or heterozygous particularly by means of still another recently discovered blood factor the Hr factor. It has been shown that individuals whose blood is Hr negative are homozygous for the Rh factor at least so far as the clinical results are concerned.⁸

Technic employed by Dr. Lowell Erf, Hematology Division, Jefferson Hospital Philadelphia.

2 Where an Rh incompatibility exists, the first pregnancy frequently escapes or the erythroblastosis is not severe because the process of immunization requires time to develop. If the patient has been "sensitized" by a previous transfusion of Rh positive blood the mechanism may operate at once. Repeated transfusions of Rh positive blood may give rise to a "transfusion" reaction, explaining many hitherto puzzling transfusion reactions.

3 Although one in seven individuals is Rh negative, according to Wiener only about one in fifty of these is readily sensitized.

4 Occasionally a normal fetus is born despite active isoimmunization of the mother as indicated by the presence of a high titer of Rh agglutinins in her blood. On the other hand, Levine⁵ states that in 8 per cent of erythroblastotic infants the mothers are Rh positive but isoimmunization may have resulted from (a) finer differences in the Rh factor, (b) properties A or B of fetal blood, (c) nonsecretory type, or (d) Hr factor.

In pregnancies of Rh-negative women married to Rh-positive husbands, testing the maternal blood at intervals throughout gestation for *Rh antibodies* is a helpful procedure in determining whether isoimmunization is occurring. In this agglutination reaction, the maternal serum is used as the testing serum against known suspension of Rh-positive red cells. By using various dilutions of maternal serum the "titer" of the Rh antibodies can be determined. In Rh negative women who have been pregnant before or previously transfused, it is wise to test for antibodies before the onset of pregnancy, since such antibodies may persist for a considerable time. An increasing antibody titer as pregnancy progresses usually indicates active isoimmunization and usually indicates an unfavorable prognosis. If the fetus reaches viability, interruption of the pregnancy in an attempt to obtain a live baby is sometimes advocated. All preparations should be made to transfuse the baby at once with Rh-negative blood free of Rh antibodies. Blood from the mother should *never* be used.

Wiener has recently pointed out that in some instances Rh antibodies cannot be demonstrated by the usual agglutination reaction because they are present in a "blocked" form. He has described a "blocking test" by which these antibodies can be demonstrated.⁸

It is generally agreed that Rh incompatibility is not an important cause of habitual abortion and miscarriage but that it becomes a factor only in the latter half of pregnancy.

CYTOLOGY OF VAGINAL SMEARS

(With Particular Reference to Ovarian Function and Uterine Cancer)

Examination of the cells found in vaginal smears has become one of the most useful laboratory procedures for the gynecologist. Many years of persistent study of human vaginal cytology by Papanicolaou and more recently by others have shown that much can be learned concerning ovarian function, tumors and other diseases of the genital tract by examining the cells which have been shed from the genital tract and have collected in the vagina. Indeed, it would seem that ade-

quate examination of such smears bears the same diagnostic significance in regard to the genital tract as does the routine urinalysis to the urinary tract

So far as ovarian function is concerned, the staining procedure and the examination of the smear can be simplified to take but a few minutes for each slide, and even the novice can quickly learn to interpret the more significant findings. On the other hand, the preparation of smears for the diagnosis of uterine cancer requires much more detailed technic. Furthermore, the proper interpretation of such smears requires a considerable experience in recognizing the many types of cells which can be found in even normal women, their site of origin, the less common cells found in various functional and benign lesions of the genital tract, as well as the characteristics of cells that arise from malignant lesions. It is gratifying, however, that the more time one devotes to the study of these smears, the more fruitful become the results of each succeeding examination.

Preparation of Vaginal Smears—It is preferable that the patient does not douche on the day on which the smear is to be taken. A slightly curved glass pipette, 6 to 8 inches in length and about 0.5 cm. in diameter, with a rounded narrow tip and attached to a strong rubber bulb of 1 or 2 ounce capacity, for producing suction, is used for collecting the secretion. The rubber bulb is compressed, the glass pipette is introduced into the posterior fornix of the vagina and the vaginal secretion is sucked into the pipette. The tip of the tube is moved from one side of the fornix to the other so that all parts are sampled. The material thus collected is blown on the surface of a clean microscope slide and further spread with the convex side of the pipette. *Before the smear can dry* the slide is immediately dropped into a Coplin jar containing equal parts of 95 per cent alcohol and ether. Although fixation does not require more than a few minutes, the slides may be kept in the fixative, without harm, for as long as a week.

Staining Vaginal Smears.—1 *For Ovarian Function*—Smears that are to be examined only for ovarian function can be stained by a simplified procedure using prepared differential stains such as suggested by Papanicolaou^{9*} or Shorr^{10†}

The Shorr stain (S3) has the following formula

Biebrich Scarlet (water sol.)	0.5	gm.
Orange G	9.25	gm.
Fast Green FCF	0.075	gm.
Aniline Blue (water sol.)	0.04	gm.
Phosphotungstic and Phosphomolybdic Acids CP	22 0.5	gm.
Glacial Acetic Acid	1.0	cc.
Dissolve all completely in 50 per cent ethyl alcohol	100	cc.

* Stain (EA50) can be obtained from Ortho Pharmaceutical Corp., Linden, New Jersey

† Single Differential Stain (Shorr) can be obtained from Wyeth Incorporated, Philadelphia.

The latter stain may be applied by dropper for one to two minutes, the slide is then dipped ten times in 70 per cent, 95 per cent and absolute alcohol (may be omitted by blotting after 95 per cent alcohol), well cleared in xylol and mounted

Fig 197—Vaginal smear from a menopausal woman showing marked estrogen deficiency as indicated by large numbers of small, round, green staining cells from the basal layer of the vagina

Fig 198—Vaginal smear from a young woman at the midcycle showing good estrogen effect as indicated by large squamous epithelial cells most of which are partially cornified and take an orange-red stain

The "atrophic cells," small in size, rounded in shape, take the lavender stain (Fig 197) Under estrogenic influence the larger squamous epithelial cells appear and are of green color, while with full cornification, the squamous cells assume a brilliant orange red hue (Fig 198) More detailed study of the morphology permits further evaluation of

the estrogenic effect. The experienced observer often can note changes in day to-day smears suggestive of corpus luteum function as well, although there are no specific criteria of progesterone function.

During pregnancy the cells tend to become elongated, concave or navicular, or totally vacuolized and the nucleus often elongated or collapsed.¹¹ Regression of these changes and the appearance of red cells is often noted in threatened abortion or impending parturition.

2 For the Diagnosis of Uterine Cancer—Papanicolaou has devised many stains and techniques to yield the excellent cytologic detail necessary for studying malignant cells. A very satisfactory procedure suggested by Papanicolaou⁹ is as follows:

1 Fix smears before drying in equal parts of 95 per cent alcohol and ether for five minutes or longer. Rinse in 70 per cent and 50 per cent alcohols and in distilled water.

2 Stain in hematoxylin for five to ten minutes. Rinse three to four times in 0.5 per cent aqueous solution of HCL. Rinse thoroughly in water. Leave for one minute in a weak solution of lithium carbonate (3 drops of a saturated aqueous solution per 100 cc. of water). Rinse thoroughly in water.

3 Rinse in distilled water then in 50, 70, 80 and 95 per cent alcohols.

4 Stain for one minute in solution OG 6 consists of Orange G (National Aniline and Chemical Co.) 0.5 per cent solution in 95 per cent alcohol, 100 cc., and phosphotungstic 0.025 gm.

5 Rinse five to ten times in each of two jars containing 95 per cent alcohol to remove excess stain.

6 Stain for two minutes in EA36

Light Green (0.5 per cent solution in 95 per cent alcohol) 45 cc.

Bismarck Brown (0.5 per cent solution in 95 per cent alcohol) 10 cc.

Eosin Yellowish (0.5 per cent solution in 95 per cent alcohol) 45 cc.

Acid Phosphotungstic 0.200 gm.

Lithium Carbonate (Saturated Aqueous Solution) 1 drop.

7 Rinse five to ten times in each of three jars containing 95 per cent alcohol. Rinse in absolute alcohol. Mount in Canada Balsam.

It has already been emphasized that it is necessary to be thoroughly familiar with the normal cells of the vaginal mucosa, cervix and endometrium before attempting to recognize the atypical malignant cells. Excellent descriptions and drawings can be found in the monograph by Papanicolaou and Traut.¹²

The diagnosis of carcinoma of the cervix depends upon finding atypical cervical cells in which there is great variation from the normal in size, shape and form and especially with abnormalities in the size, form and staining reaction of the nuclei (Figs. 199 and 200). Many varieties of abnormal and bizarre cells may be found depending upon the type of malignancy, degree of activity, degenerative changes and the like. Red blood cells or evidences of bleeding are almost invariably present and usually there are many leukocytes and histiocytes.

The diagnosis of endometrial carcinoma by the vaginal smear

method is much more difficult. The cells seen are much like those noted in sections of the tumor. The abnormal endometrial cells are on the average larger than the normal endometrial cells and also show greater variation in the size of the nuclei. The nuclei are usually hyperchromic, mitoses are not common.

Fig 199—A typical "tadpole" cell from a patient with cervical carcinoma. Note the bizarre shape of the cell and the abnormally large hyperchromic nucleus.

Fig 200—A group of cervical cancer cells of the "prickle cell" variety showing abnormality in size, shape and staining reaction with marked variation in the nuclei.

The value of the vaginal smear method as a diagnostic procedure to determine cancer remains to be determined. In the hands of experienced workers it appears to be of value as an aid in directing suspicion upon cases worthy of further investigation. It is not at present intended as a method for establishing an absolute diagnosis of cancer.

or for replacing biopsy, rather it aims to uncover cases which should be studied by biopsy. The most encouraging reports of all concern the cases in which "positive" smears were obtained in very early lesions which were missed on clinical study or even by biopsy^{12, 13}

TESTS FOR PREGNANCY

Of the various laboratory procedures which have been offered for the diagnosis of pregnancy, those based on the demonstration of a *high titer of chorionic gonadotropic hormone in the blood or urine* continue to be the most generally acceptable. In addition to the well established Aschheim-Zondek and Friedman tests, several other techniques based on this same principle have recently been described including the "frog test" and several rapid rat tests.

South African Frog (*Xenopus laevis*) Test—When the female South African frog (*Xenopus laevis*) is injected with chorionic gonadotropic hormone such as is present in the blood or urine of pregnant women, eggs are extruded within six to eighteen hours. This species of frog is peculiarly suited for this test in that it carries eggs in its abdomen throughout the year rather than only at mating time. The animals do not regularly react to small amounts of chorionic gonadotropin. The injection of larger amounts of hormone therefore requires initial concentration of the hormone in the urine specimen.

Procedure¹⁴—To 80 cc. of urine twice the volume of acetone is added. The mixture is thoroughly stirred and allowed to stand for fifteen minutes or longer to precipitate the proteins. The precipitate which contains the gonadotropic hormone is collected by decanting and centrifuging. The precipitate is allowed to dry. The hormone is then extracted by adding 2 or 3 cc. of distilled water, stirring thoroughly and centrifuging or filtering. One half of the recovered supernatant (representing 40 cc. of urine) is injected into the dorsal lymph sac space of the frog by means of a short needle. Care must be taken to avoid puncturing the lungs. It is preferable to inject two frogs for each test. Only mature, healthy, well nourished female animals should be used, preferably those which have reacted previously to chorionic gonadotropic substance. The animals may be used again after a week if the test is negative or after a month following a positive test. The animals are left in tanks at room temperature ($70^{\circ}\text{F} \pm 5$) with water at a level of about 3 inches. They are fed small strips of beef heart or calves liver twice a week. Before testing they are placed in individual tanks fitted with a wire mesh platform to permit the extruded eggs to fall through without danger of the frog devouring the extruded eggs.

The advantage of the frog test, of course, is its rapidity, this makes it particularly useful in cases of suspected ectopic pregnancy and other surgical emergencies involving possible pregnancy. The ease with which the test is read is also of advantage. The chief disadvantage in our experience is that the animals sometimes become refractory and fail to respond to relatively large amounts of chorionic gonadotropic hormone, thus giving "false negative" tests. We have

never encountered a "false positive" The necessity for preliminary concentration of the urine is another disadvantage, as is also the present difficulty in obtaining the animals and their initial expense

Rapid Rat Tests for Pregnancy—The earliest reaction produced by chorionic gonadotropin in the rat ovary is a hyperemia which may appear within two to six hours and which has been used as the basis of a hormone test for pregnancy by a number of workers employing various technics

Procedure—Zondek and co-workers,¹⁵ in a recent review of the subject, suggests that 2 cc of urine should be injected subcutaneously into infantile female rats (three to five weeks old) in two injections of 2 cc each at an interval of one hour One rat is killed after six hours and the other two are killed in twenty-four hours, preferably with illuminating gas The reaction is positive if hyperemia (nearly "strawberry red" color) appears in at least one ovary of two different rats For the beginner, noninjected rats should be used as a control Zondek found that reading the test at two hours gave a 15 per cent error, at six hours a 78 per cent error, while at twenty-four hours there was a 1 per cent error (all false positives)

In our own experience with the hyperemia tests, we have not been highly successful There was frequently a difference of opinion in the laboratory as to whether the ovaries of a given test were sufficiently pink to constitute a positive test Differences in the age and strain of animals were also found to be important factors in the reliability of the reaction

"Chemical Tests" for Pregnancy—Unfortunately no suitable color reaction or other chemical test which is specific for chorionic gonadotropin has been discovered Tests for other substances in the urine of pregnancy have been described from time to time but have not proved to be generally satisfactory because they lack specificity Except for chorionic gonadotropin, there is no other known substance which is specifically produced in large amounts in early pregnancy

Recently Guterman¹⁶ has described a simplified color reaction for pregnandiol in the urine as a diagnostic procedure for pregnancy The test is based on the principle that if pregnandiol is present in an amenorrheic patient, pregnancy is possible

The method, which is too lengthy to be given in detail here, consists essentially of the extraction with toluene of the acid-hydrolyzed pregnandiol complex of urine, followed by the purification and precipitation of the pregnandiol The characteristic orange to orange-brown color is developed by sulfuric acid Four to six such tests can be run simultaneously by one person in three hours

In our experience, pregnandiol color reactions, although considerably better than other chemical tests for pregnancy, have not proved sufficiently accurate to compare favorably with the Friedman or Aschheim-Zondek procedures In early pregnancy the pregnandiol concentration is sometimes not sufficiently high to be readily demon-

strable by the method described, on the other hand, in some instances of delayed menstruation, pregnandiol or pregnandiol-like substances have been present in sufficient amounts to give false positive reaction.

Chemical tests based on the demonstration of increased titers of estrogens, as an indicator of pregnancy, are not recommended as a reliable procedure for the diagnosis of early pregnancy. Late in gestation the estrogen level becomes sufficiently high to make estrogen tests of more significance.

Colostrum Test for Pregnancy—Falls and his associates¹⁷ noted that pregnant women failed to develop a local reaction around the site of an intracutaneous injection of colostrum in contrast to a wheal found in non-pregnant patients. They advocated the procedure as a test for pregnancy. It has not been found by most workers to be sufficiently accurate to constitute a satisfactory diagnostic test.
